Acoustic Communication Studies (U)

Chairwoman V. Konatz

(Received Aug. 29, 1974)

Pacific Geophysical Institute, Miami, Fla.

- (U) **(P)** An experimental study of coherent, matched filter techniques for submarine-to-subsurface communication was conducted. Coherent, matched filter techniques offer three advantages over existing systems. First, coherent, matched filter techniques allow a signal-to-noise ratio, significantly below 0 dB, to produce a system performance as high as a signal-to-noise ratio which current systems require in deepwater conditions. Second, filtered receiver techniques used with a filter matched to the received signal were used to minimize the effects of both noise and multipath. Finally, these techniques are compatible with a standard, standardized transmission format, which reduces the detectability of the signal by unclassified receivers. The research program was conducted in two stages. The first stage evaluated communication system performance over 7- and 45-mile fixed-line routes. Over 4,000 hours of experimental data were obtained and analyzed to ensure the feasibility of the measurements. Results from these data showed that reliable communications could be achieved with a signal-to-noise ratio as low as 0 dB. A typical experimental system (MGB) transmitted 0.25 bits/sec in a 10-kHz band centered at 420 Hz. Over a 22-mile path, there was a 10% probability of 0.01 at an input signal-to-noise ratio of -9 dB. Research focus increased to within 0.1 dB of the optimum receiver operating frequency. Further time invariant channel with added white Gaussian noise. To determine the applicability of the fixed-line results to the submarine-to-subsurface communication problem, the second stage of the program investigated the space-time stability of the acoustic channel with a broad beam. An experiment was conducted in the deep ocean off Eniwetok, R.I., at ranges from 0 to 400 sec. This experiment indicated only a 10 percent deterioration in the channel from over 200-sec interval to the next. Consequently, the coherent, matched filter techniques evaluated over the fixed-line ranges are applicable to practical problems involving acoustic-to-subsurface communication systems using coherent matched filter techniques. A particular implementation (M7) incorporating a combined matched filter transmission for detection resistance is suggested as a basis for future work.

(U) INTRODUCTION

(U) Underwater acoustic communication systems based on coherent, matched-filter techniques have been studied experimentally. Although the specific goal of the research was tactical submarine-to-subsurface communication systems, the results are applicable to other situations. This paper describes extensive fixed-beam communication experiments and an important transmission measurement that encourage the immediate consideration of these techniques for submarine communication systems.

- (U) **(P)** Coherent, matched-filter techniques offer three distinct advantages for submarine communication systems. First, coherent integration allows satisfactory operation at low signal-to-noise ratios,

without the threshold effect that is common to incoherent systems. Second, matched-filter operation reduces the effects of both noise and multipath under varying propagation conditions. And finally, these techniques are compatible with a standard transmission format that reduces the detectability of the communication signal.

- (U) **(P)** The processing techniques employed in the research are based on well-established theory. The acoustic medium is assumed to approximate a linear, time-invariant channel with added white Gaussian noise. For such a channel, the optimum receiver is composed of a filter matched to the received signal, followed by a threshold device. The matched filter can also be shown to reduce inter-symbol interference caused by multipath. One of

List of Symbols

$a_{k,l}$	all sequence coefficient.
$a_{k,l}^+$	probe component of k th frame.
$a_{k,l}^-$	information component of k th frame.
$a_{k,l}^0$	integrated probe component.
$b_{k,l}$	biphase sequence coefficient.
c_l	average speed of sound.
$d_{k,l}$	estimated average period of wavelet.
$d_{k,l}^+$	decision on the k th symbol of the k th frame.
$d_{k,l}^-$	prioritized decision on the k th symbol of the k th frame.
d_k	bit frame.
E	output signal-to-noise ratio.
E_d	bit information rate.
E_s	other output on probe component.
E_i	error count on information component.
E_c	cumulative error count.
E_x	expected value of x .
F	Doppler-shifted carrier frequency.
f_m	reciever center frequency.
f_m^+	transmitted symbol waveform.
f_m^-	transmitted waveform for the k th symbol.
f_m^0	recived symbol waveform.
$f_{k,l}$	recived waveform for the k th symbol.
$f_{k,l}^0$	1D sample component factor.
$f_{k,l}^-$	number of sequence periods per frame.
$f_{k,l}^+$	number of information symbols per frame.
$f_{k,l}^0$	number of probe frames per measurement interval.
f_m	number of digits per symbol.
f_m^0	number of digits per sequence period.
$f_{k,l}^0$	matched filter output for the k th digit of the k th frame.
$f_{k,l}^-$	unmatched waveform.
$f_{k,l}^+$	probe component of transmitted waveform.
$f_{k,l}^0$	information component of transmitted waveform.
f_m	noise component waveform.
f_m^0	noise waveform sample.
f_m^+	noise waveform from probe component.
f_m^-	noise component of matched filter output.
f_m^0	degree of linear minimum sequence.
f_m^+	number of symbols per frame.
f_m^-	number of digits per frame.
f_m^0	number of multiplications per frame.
f_m^+	number of samples per sequence period.
f_m^-	noise power in the k th measurement interval.
$f_{k,l}^0$	received digit waveform.
$f_{k,l}^-$	calculated received digit waveform.
$f_{k,l}^+$	target probability.
F	symbol composition coefficient for the k th
F_d	digit of the k th symbol.
F_s	offset between signal and vvv spectral lines.
F_c	integer offset between signal and vvv spectral lines.
$R_{m,n}$	value of r which maximizes SNR.
$R_{m,n}^0$	SNR criterion between $s(t)$ and $r(t)$.
$R_{m,n}^+$	multiplication rate.
$R_{m,n}^-$	signal component waveform.
$R_{m,n}^0$	signal component waveform sample in k th interval.
$S(k,l)$	discrete Fourier transform of $a(k,l)$.
$S(k,l)^+$	signal power in the k th measurement interval.
$S(k,l)^-$	input signal-to-noise ratio.
$S(k,l)^0$	output signal-to-noise ratio as $a(k,l)$ vector.
T	digit duration.
T_m	duration of probe frame plus information frame.
T_m^0	frame duration.
T_m^+	duration of measurement interval.
T_m^-	duration of reception of input.
T_m^0	Doppler-discriminated segment duration.
T_m^+	symbol duration.
T_m^-	sequence-period duration.
T_m^0	transmitted digit waveform.
T_m^+	unit step function.
T_m^-	source Doppler velocity.
V	maximum expected range Doppler velocity.
W	systems bandwidth.
W_m	low pass system bandwidth.
$x(k,l)$	received waveform.
$x'(k,l)$	sample of received waveform.
$x(k,l)^0$	comprised sample of received waveform.
$x(k,l)^+$	probe component of received waveform.
$x(k,l)^-$	received waveform from infinitely long probe periodically extended probe component of received waveform.
$x(k,l)^0$	information component of received waveform.
$x(k,l)^+$	complex, conjugated sample of received waveform.
$X(k,l)$	discrete Fourier transform of $x(k,l)$.
$\chi(k,l)$	phase variance.
$\chi(k,l)^0$	chi-squared probability distribution.
$\chi(k,l)^+$	normal cumulative probability distribution.
$\chi(k,l)^-$	decision threshold on k th symbol of k th frame.
$\chi(k,l)^0$	performance difference.
$\chi_{k,l}(t)$	frequency offset between signal and vvv lines.
$\chi_{k,l}^0$	normalized cross correlation function.
$\chi_{k,l}^+$	k th continuity coefficient from September 1973 experiment.
$\chi_{k,l}^-$	sample of normalized cross correlation function in k th measurement interval.
$\chi_{k,l}^0$	correlation coefficient in k th measurement interval from January 1974 experiment.
$\chi_{k,l}^+$	interval longer in z .

The most interesting results of the research is the agreement obtained between the experimental data and the predictions of this theory.

- (U) (V) Because the physical channel is distinctly time-varying, the received symbol waveform must be continuously measured to maintain the required match between the filter and the symbol waveform. This measurement is made possible by including a known probe component in the transmission in addition to the unknown information component. Thus, the communications systems described here perform dual role—channel measurement and information transmission.

(U) The experimental program has two closely related stages. The first stage conducted communication experiments between fixed sites to obtain a statistically significant quantity of performance data. Table I depicts the history of the fixed-site communications experiment. Only the results of the recent experiments, M5 and M6, are presented here. Previous experiments obtained similar results, but they were based on very few data.⁽²⁾ Sections II, III, and IV of this article detail the operation and performance of the M5 and M6 experiments.

(U) The second stage of the experimental program was to determine the applicability of the fixed-site results to the submarine communications problem.

For such an application to be possible, the acoustic medium must be stable in space as well as time. That is, the probe measurement of the channel must remain valid under spatial displacement of the submarine platform. Consequently, a careful measurement of the spatial stability was made, as described in Section V.

- (U) (V) The nature of the results from the fixed-site communications experiments and the spatial stability measurements solidly indicates the feasibility of coherent, matched-filter techniques for submarine communications systems. These conclusions and others are presented in Section VI. An application of these techniques in conjunction with a randomized transmission format is also given.

II. TRANSMISSION FORMAT

- (C) (U) Because of the dual nature of the transmission and the implementation of the receiver processing,

TABLE I. Summary of fixed-site communications experiments. (Table undated.)

Experiment	Year	Budget (mn\$)	Duration (hr)
M1	1968	7	24
M2	1969	7	24
M3	1969	7	24
M4	1970	42	4
M5A	1972	7	2214
M5B	1972	7	1560
M6A	1973	62	658
M6B	1973	62	594
M6C	1973	62	162

the signals transmitted by the communication systems have a complicated format. One part of the signal, the probe component, allows measurement of the channel; the other, the information component, contains the information. Subsequent parts of this section describe these components in detail and explain the choice of transmission format. Section III on receiver processing completes the explanation. The probe and information components are transmitted interleaved in time (time multiplexed) as described in Section IIa.

A. BASIC WAVELET ELEMENT, THE BEAR

(U) Both components of the transmission are composed of a succession of biphasic modulated elements, called digits. The simplest example of a digit waveform is a rectangular carrier pulse. The probe and information components consist of modulated digits in a prescribed (or in the case of the information component, almost prescribed) order. In the subsequent discussion, no conflict will arise if the digit waveform is assumed to be a rectangular carrier pulse, although in practice, some amount of bandspreading of the digit is desirable, as suggested below.

- (U) For a rectangular carrier pulse, the pulse duration and bandwidth are inversely related; that is, once the duration is specified, the bandwidth is also fixed. This constraint is undesirable in practice, since the choice of digit duration and digit bandwidth is based on different considerations. Typically, the digit duration is

UNCLASSIFIED

UNCLASSIFIED

~~CONFIDENTIAL~~

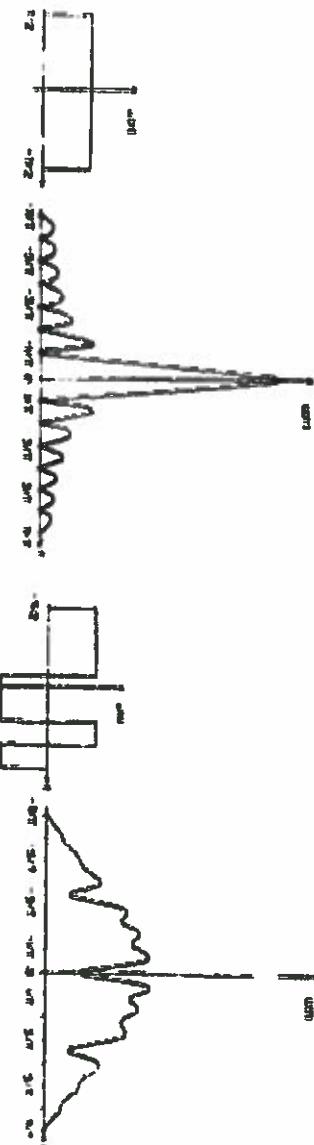

Figure 1c. Digit waveform: band-pulsed digit with zero subsymbols. (Figure unclassified)

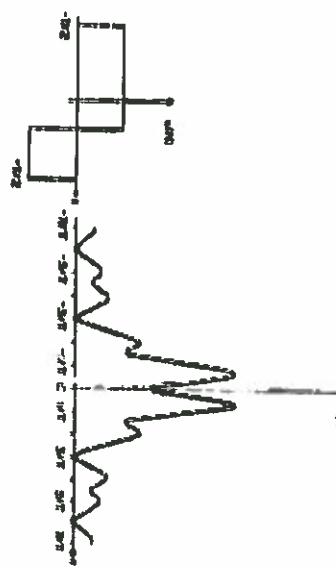

Figure 1b. Digit waveform: band-pulsed digit with three subsymbols. (Figure unclassified)

(c) In general, the problem is to increase the digit bandwidth beyond that of a rectangular digit of equal duration. Figure 1 shows the results of band-pulsing of the digit waveform by comparison with a rectangular pulse and its spectrum in Fig. 1a. In each part of Fig. 1, $u(t)$ is the digit waveform and $U(f)$ is the digit spectrum. Note that as the number of subelements in the digit waveform is increased, the bandwidth increases proportionately. The digit waveform in Fig. 1b was used in the M1, M2, M3, and M4 experiments, and the waveform in Fig. 1c was used in the M6B and M6C experiments.

b. PROBE CONTEXT
(c) ~~M~~ The probe component of the transmission allows the receiver to measure the channel digit

response. Because the information symbols are composed of combinations of digits, a filter matched to the symbols can be formed from the digit response. The probe component must be constant and known to the receiver if this measurement is to be successful. This is in contrast to the information component, described later in Section IIc, which is inherently variable and unknown.

(D) One method of measuring the channel digit response is to transmit a single, isolated digit as the probe component, as shown in Fig. 2a. Vacant time intervals must be inserted before and after the probe digit to allow for the time smear of the probe digit to allow for the time smear of the probe structure is that energy is transmitted for only a small fraction of the probe duration. Consequently, the receiver's measurement of the channel is noisy.

(E) A better choice for the probe component is to form it from an integral number of periods of a linear maximal sequence. This allows more energy to be transmitted in the probe, with a corresponding improvement in the measurement of the channel digit response.

(F) Let $u(t)$ be the transmitted digit waveform of duration T . Let $K_i(t)$ equal to either $+1$ or -1 [$K_i(t) \pm 1$] be the values of a K_m long, linear, maximal sequence. The probe component, $s_K(t)$, of the transmission is obtained by modulating successive digits with K_m periods of the sequence.

$$s_K(t) = \sum_{i=1}^{K_m-1} K_i u(t - iT) \quad (1)$$

where

$$N_m = K_m \cdot K_m \quad (2)$$

UNCLASSIFIED

~~CONFIDENTIAL~~

UNCLASSIFIED

~~CONFIDENTIAL~~

The transmitted probe component will be time-limited to a duration $T_{\text{fm}} = N_m \cdot T$, because of the limited duration of the individual digits. A probe component of this form is shown in Fig. 2b for $K_m = 1$ and $N_m = 15$.

(1) Because of the assumed linearity of the word-bit channel, the received probe $r_p(t)$ is a superposition of channel digit responses, $p(t)$:

$$r_p(t) = \sum_{i=1}^{N_m} K_i p(t-iT) \quad (3)$$

In general, time smearing of the channel will make the duration of the received probe longer than T_{fm} .

(11) The primary objective of the probe component $p(t)$, to allow measurement of $p(t)$; and consequently $p^*(t)$, as indicated in Eq. (3), must be processed further to be useful. A simple digital filter can be applied to $r_p(t)$ to obtain a waveform $\hat{p}(t)$, which approximates the channel digit response $p(t)$. To understand the derivation of the approximate channel response $\hat{p}(t)$, consider the following analysis for an infinitely long periodic probe component, $p^*(t)$

$$p^*(t) = \sum_{i=-\infty}^{+\infty} K_i p(t-iT) \quad (4)$$

Define $\hat{p}^*(t)$, the calculated channel response, as follows:

$$\hat{p}^*(t) = \frac{\sum_{j=0}^{K_m-1} K_j + 1}{2} p(t+jT) \quad (5)$$

Note that, although $\hat{p}^*(t)$ is of infinite extent, the summation for $\hat{p}^*(t)$ involves only N_m terms.

(11) If Eq. (4) is inserted into Eq. (5), the following expression is obtained:

$$\hat{p}^*(t) = \sum_{i=1}^{N_m-1} \sum_{j=0}^{K_m-1} \frac{K_j + 1}{2} K_i p(t-(i-j)T) \quad (6)$$

After a change of variables, $k = i - j$, Eq. (6) becomes

$$\hat{p}^*(t) = \sum_{k=1}^{N_m-1} K^{k+1} \sum_{j=0}^{K_m-1} \frac{K_j + 1}{2} K_{k+j} \quad (7)$$

Figure 2. Probe component structures. (Figure and figure caption each classified CONFIDENTIAL)
a) $p(t)$
b) $\hat{p}(t)$

Because of the properties of linear maximal sequences, the summation over j is known:

$$\sum_{j=0}^{K_m-1} \frac{K_j + 1}{2} K_{j+k} = \frac{K_{k+1}}{2} \cdot K_m \quad (8)$$

for $k = 0, K_m, 2K_m, \dots$

$$\sum_{j=0}^{K_m-1} \frac{K_j + 1}{2} K_{j+k} = 0 \quad (9)$$

otherwise. With the above results substituted into Eq. (7), the following simplified expression is obtained:

$$\hat{p}^*(t) = \frac{K_m + 1}{2} K_m \sum_{k=1}^{N_m-1} p(t-K_m \cdot kT) \quad (10)$$

That is, $\hat{p}^*(t)$ is a periodic (with period $T_m = K_m \cdot T$) replica of $p(t)$ with a processing gain of $K_m \cdot (K_m + 1)/2$. Consequently, with an infinitely long probe component, Eq. (5) allows the exact measurement of the channel digit response.

~~CONFIDENTIAL~~

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

- (c) $\rho(t)$ The probe component, $s_p(t)$, for an actual communication system cannot have infinite extension, as does $s_p^*(t)$. However, a periodic extension, $s_p^*(t)$, can be constructed from $s_p(t)$ to yield an approximation to $\rho(t)$. Assume that most of the energy of $s_p(t)$ is contained in the time interval $[t_0, t_0 + T_m]$. Consider the infinite periodic extension, $s_p^*(t)$, of $s_p(t)$ in this interval:

$$s_p^*(t) = s_p(t); \quad t_0 \leq t < t_0 + T_m \quad (11)$$

$$= s_p(t - kT_m); \quad t_0 + kT_m \leq t < t_0 + (k+1)T_m \quad (12)$$

If $K_m > 1$ and the time duration of $\rho(t)$ is small relative to the sequence duration, $T_n = K_m \cdot T$, then

$$\rho^*(t) \cong s_p^*(t) \quad (13)$$

So an approximation to $\rho(t)$ is calculated as:

$$\hat{\rho}(t) = \sum_{j=0}^{K_m-1} \frac{K_m}{2} s_p^*(t-jT_m); \quad t_0 \leq t \leq t_0 + T_m \quad (14)$$

$$\cong \frac{K_m+1}{2} \cdot K_m s_p(t); \quad t_0 \leq t < t_0 + T_m \quad (15)$$

That is, $\hat{\rho}(t)$ is approximately equal to $\rho(t)$ multiplied by a constant. This constant gives a significant preserving gain against noise.

- (c) In the M15 and M6 systems, K_m was selected during the system design stage to be 15, so T_m exceeded the expected range of $\rho(t)$ by a factor of at least three. The constant K_m was selected to be four so as to support the approximation indicated by Eq. (13). With these parameter values, the use of the coded probe component yielded a 9-dB preserving gain over a single digit probe repeated K_m times. No adverse effects due to the approximation were observed.

c. INFORMATION COMPONENT

- (c) The information component can be factored in one of three ways: (1) biphase modulation of single transmitted digits; (2) biphase modulation of groups of digits, where the intragroup structure is constant; or (3) variable symbol modulation, in which biphase modulation of groups of digits, where the intragroup structure varies from one symbol to the next, is carried out.

CONFIDENTIAL

- (c) In the subsequent discussion, the difference between a digit—described previously—and a symbol is important. A symbol is a digit or group of digits used to carry a single bit of information. The objective of the receiver is to determine symbol values, not digit values; thus, the difference between the two methods of forming the information component lies in the structure of the symbol waveform.

1. Single Digit Symbols

- (c) The simplest construction of the information component assigns a single digit to each symbol. A digit transmitted at 180-degree phase represents a binary-minus one. This technique was used in the M1, M2, M3, and M4 systems.

- (c) In all of the systems considered, the number of digits in the information component was made equal to the number of digits in the probe component. When the probe component contained K_m repetitions of the K_m -digit linear maximal sequence, the information component was composed of K_m repetitions of K_m information-bearing "spins." This symmetric structure is arbitrary, and it effectively sets the information and probe component energies equal. In general, the structures of the probe and information components are independent, subject only to the constraint that both be composed of the same digit waveform. Thus, the k th transmitted information component $s_k(t)$ is given by

$$s_k(t), \quad \sum_{i=0}^{K_m-1} \sum_{j=0}^{K_m-1} c(K_m - k + j) \rho(-(K_m - i + j)T) \quad (16)$$

where $c[i][j] \pm 1$ is the i th information bit.

- (c) Figure 3a depicts an information component using a single digit per symbol. The diagram shows K_m symbols corresponding to the information stream $-1+1-1+1+1, -1-1+1-1-1, -1+1+1+1+1$. Only one repetition ($K_m = 1$) is shown for simplicity. In actual practice K_m is taken as being larger than one to increase the energy content of each symbol and to provide limited time diversity.

2. Multiple Digit Symbols

- (c) If each information symbol is composed of only one digit, as described above, then potential

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

inkoff opportunities for system design are eliminated. For example, the number of digits in the sequence, K_m , and the digit duration, T_d , must be selected so that the time duration of the received digit, $\mu(t)$, is less than the sequence period, T_m , in order to properly measure $\mu(t)$. Because of memory requirements in the receiver, the sequence period, T_m , should be as short as possible. However, the resulting digit duration, T_d , may be too small to provide adequate symbol energy and to avoid intersymbol interference.

(c) (c) One solution to the above problem is to simply allow more than one digit per symbol, keeping the digit duration, T_d , and K_m constant. In the 15 and 16 systems, three digits were used for each information symbol, giving a threefold increase in both symbol energy and duration, with no increase in sequence duration, T_m .

(c) (c) The composition of the information symbol is arbitrary, as long as it is composed of fixed combinations of digit waveforms. Let $g(t)$ be a symbol that is taken as being composed of K_m digit waveforms,

$$g(t) = \sum_{i=0}^{K_m-1} g(i) \alpha(t-iT) \quad (17)$$

where $g(i) \in \{0, \pm 1\}; i=0, \dots, K_m-1$. The choice of digit separations of multiples of T sec and unity magnitude for the $g(i)$'s is not essential in general but it was made for ease of generation and processing of the signal. If $\mu(t)$ is the received digit response, then a filter, $A(\mu)$, matched to the received symbol is

$$h(t) = \sum_{i=0}^{K_m-1} g(i) \mu(t-iT) \quad (18)$$

by the assumed linearity of the channel. Thus, a filter matched to a specified symbol can easily be constructed from the received digit waveform $\mu(t)$ and the symbol composition given by $g(0), \dots, g(K_m-1)$.

(d) Figure 3b depicts an information component with $K_m=3$ digits per symbol and with $g_1=1$, $g_2=1$, and $g_3=-1$. The information values shown are $-1+1-1+1+1$. Again, $K_m=1$ for the sake of simplicity.

— CONFIDENTIAL —

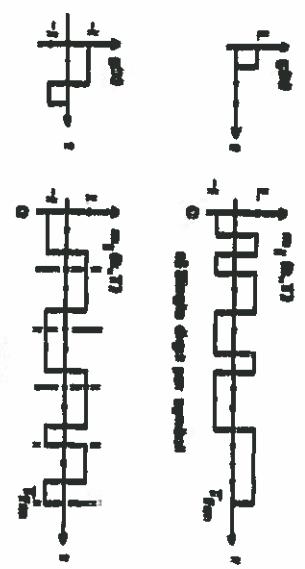

Figure 3. Information component structure. (Figure 3a) shows a symbol waveform $g(t)$ consisting of three digits per symbol.

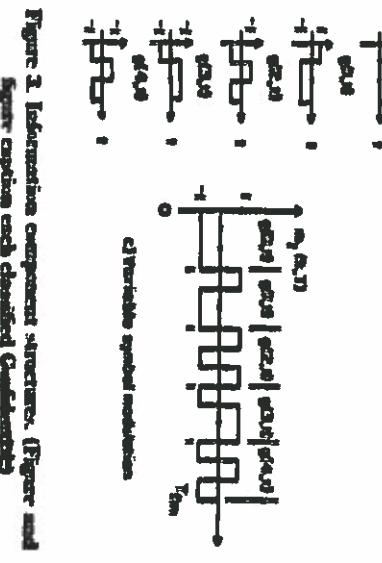

Figure 4. Four symbol modulations. (Figure 4a) shows four symbol waveforms g_1, g_2, g_3, g_4 .

3. Variable Symbol Modulation

(e) If more than one digit is contained in each symbol, as described above, the opportunity to alter the symbol composition from one time interval to the next arises. For example, consider K_m consecutive symbols having K_m digits per symbol. The job symbol waveform is specified by K_m coefficients, $g(0), \dots, g(K_m-1)$, $g(i) \in \{\pm 1\}$, giving a possibility of 2^{K_m} different symbol waveforms. There is no requirement that successive symbols have the same composition, so one could define K_m symbol waveforms $g(j), j=0 \dots K_m-1$, each with different composition.

$$g(j, t) = \sum_{i=0}^{K_m-1} g(i, j) \alpha(t-iT); \quad j=0 \dots K_m-1 \quad (19)$$

to be transmitted $T_m=K_m T$ sec apart. Because of the assumed linearity of the channel, a filter matched to each symbol, $A(g_j)$, can easily be

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

extracted from $p(t)$. The k th transmitted probe response $m(t, k)$ is then

$$m(t, k) = \sum_{i=0}^{K_m-1} \sum_{j=0}^{K_a-1} s(K_m \cdot k + j) \times g(i, t - j \cdot T_m - iT_m) \quad (20)$$

The technique in which the symbol composition is permitted to vary from one symbol to the next is called variable symbol modulation.

(U) *K₁*) Variable symbol modulation was incorporated into the M5 and M6 communication systems as a means of fortifying the experimental measurement of system performance. In Section VIa, variable symbol modulation is shown to be an important component of a detection-resistant transmission format. In the M5 and M6 systems, the product of K_m and K_a was selected to equal K_m , specifically, $K_m=3$, $K_a=5$. Under these conditions, the probe and information components can be made identical by a proper choice of $g(i, j)$ and the information values $s(i)$.

(U) *h5* Let

$$q(j, i) = h(K_m \cdot j + i)$$

where $h(j)$, $j=0 \dots K_m-1$ and $i=0 \dots K_a-1$ are the biphasic sequence coefficients described in Section IIa. Then if $s(j)=1$, for all j , the transmitted information component is

$$m(t, i) = \sum_{j=0}^{K_m-1} \sum_{k=0}^{K_a-1} q(K_m \cdot k + j) \sum_{z=0}^{K_a-1} q(i, z) \times s[t - (iT_m + jT_m + zT)] \quad (21)$$
$$= \sum_{j=0}^{K_m-1} \sum_{k=0}^{K_a-1} h(j) q[t - (K_m \cdot i + j)T] \quad (22)$$
$$= \sum_{j=0}^{K_m-1} h(j) s(t - jT) \quad (23)$$

which is exactly the same as the probe component given by Eq. (3).

(U) The advantage of the above choice of K_m , K_a , $q(j, i)$, and $s(i)$ is that, since the probe and information components are identical, a periodic transmission is a valid system transmission. In measurement of the communication performance of the M5 and M6 systems, such a periodic waveform was transmitted. This simplified the structure of the transmitter and eliminated the need for

synchronization of the receiver during the lengthy evaluation process.

(U) Figure 3c depicts an information component with variable symbol modulation. The information values being transmitted are -1 , $+1$, -1 , $+1$, $+1$, and $K_m=1$.

(U) *h5* **A. MULTIPLEXING OF PROBE AND INFORMATION COMPONENTS**

(U) *h6* The transmission in each of the matched-filter communication systems consists of a multiples of the probe and information components. In choosing the multiplexing technique, the particular purpose of the probe component must be considered. For example, frequency multiplexing would be inappropriate in the acoustic medium, because the digit response measured in one frequency band would not be valid in another frequency band. Two suitable multiplexing techniques are time multiplexing and phase multiplexing. The M5 and M6 systems used time multiplexing, as described below. Later, in Section VIa, an application of phase multiplexing is presented.

(U) *h6* In the M5 and M6 systems, the transmission $m(t)$ was composed of a simple time multiplex of probe and information components:

$$m(t) = \sum_{i=0}^{t_0} m(t - 2T_m \cdot i) + m(t - (2i+1)T_m) \quad (25)$$

where T_m is the probe (and information) component duration and $T_m = K_m \cdot K_a \cdot T$. Thus, the transmission consists of alternating probe and information components, with each successive information component representing different information bits. Figure 4 depicts a typical transmission from the M5 and M6 systems. The information values for the information component shown in expanded form are -1 , $+1$, -1 , $+1$, -1 .

III. RECEIVER PROCESSING

(U) *h6* The receiver in the M5 and M6 communication systems performs a dual role. The first part of this dual role is to measure the existing channel digit response from the probe component of the transmission. Several additional measurements are made from the probe in order to eval-

UNCLASSIFIED

UNCLASSIFIED

—CONFIDENTIAL

state system performance. The second part of the receiver's role is to determine the transmitted symbol values. In general, time synchronization is required to direct the probe component of the transmission to the probe processing section of the receiver, etc. This synchronization is discussed in Section IIIa, while the following discussion (particularly Sections IIIa and IIIc) assumes that correct synchronization has already been obtained.

a. PRELIMINARY PROCESSING

(U) Signals from the receiver hydrophone are transmitted through linear, fixed-gain amplifiers to the processor. The gains of these amplifiers bring selected so that no clipping occurs during normal operation. At the processor side, a fixed analog filter centered on the carrier wave, 420 Hz, and with nominal bandwidth of 100 Hz removes most of the ambient noise from the signal. The output of the filter is amplified by another fixed-gain amplifier and applied to the digital processor analog-to-digital converter.

(U) The analog converter in the processor handles signals in the ± 1 -volt range and has either 8 bit (M15) or 9 bit (M16A, M16B, M16C) plus sign resolution, with the equivalent dynamic ranges being 45 and 54 db, respectively. System gains are adjusted so that normal operation occurs at roughly 10 db below the converter limit. Local skipping noise does cause overflows to occur throughout the system, but these overflows are infrequent and are easily recognized.

(U) The sampling of the bandpass input signal is controlled by a high-stability oscillator (at least 1 part in 10⁶) set for a sampling rate f_{ca} of four times (1600 Hz) the carrier frequency. The samples, $r'(i)$, are digitally processed to obtain complex low-pass samples, $r(i)$, equivalent to the original bandpass waveform.

$$r(i) = \frac{1}{K_o} \sum_{j=0}^{K_o-1} (-1)^j r'(2K_o \cdot i + j) \quad (i \text{ even}) \quad (26)$$

$$r(i) = \frac{1}{K_o} \sum_{j=0}^{K_o-1} (-1)^j \\ \times r'[2K_o \cdot (i-1) + 2j+1] \quad (i \text{ odd}) \quad (27)$$

In the above equations, K_o is the compression factor. The samples $r(i)$ with even indices can be

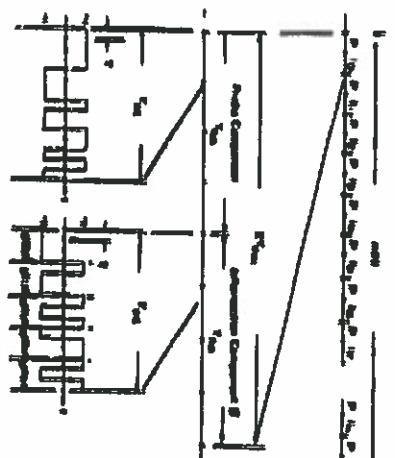

Figure 4. Typical transmission from the MU and MC systems. (Figure classified CONFIDENTIAL)

associated with the real component of the signal, and the odd indices can be associated with the imaginary component. The equivalent low-pass bandwidth R_o of either component is given by

$$R_o = \frac{f_{\text{ca}}}{4K_o} \quad (28)$$

where f_{ca} is the sampling frequency.

(U) Two additional constants will be helpful in working with the compressed samples $r(i)$ of the input waveform. The first is the number of samples per digit, N_d , given by

$$N_d = \frac{f_{\text{ca}} \cdot T}{K_o} \quad (29)$$

The second constant is the number of compressed samples per sequence period N_m :

$$N_m = K_m \cdot N_d \quad (30)$$

As will be seen shortly, N_m is an important constant in determining the memory requirements of the receiver.

b. PROBE PROCESSING

(U) The primary objective of the probe processing is to determine the channel digit response, $P(t)$. A secondary, but important, objective of the probe processing is to measure the basic transmission characteristics of the medium to aid in evaluating and understanding of the system performance. All of the communications systems included measurement of the wideband signal power and

UNCLASSIFIED

UNCLASSIFIED

CONTINUATION

noise power, SP and NP, while several specified measures of the time smear and time stability of the channel are also derived from $\hat{p}(t)$.

(J) $\hat{p}(t)$ The probe processing operator on the probe component of the transmission. At the input signal-to-noise ratios below 0 db for which the system was designed, the energy contained in a single probe component is inadequate for obtaining a satisfactory estimate of the channel digit response, $\hat{p}(t)$. Because of this, coherent integration of K_m probe components is performed, with the time interval over which it is performed being called the measurement interval. To reduce the receiver memory requirements, this integration is performed in two steps.

(J) $\hat{R}(t, i)$ The first step is to integrate over the K_m sequence periods contained in a single probe component to yield a single vector of length N_m . Let $a_s(t, i)$ be the i th element of this vector, derived from the k th probe component. That is,

$$a_s(t, i) = \sum_{k=0}^{K_m-1} s(2 \cdot k + N_m \cdot K_m + i, N_m + 1) \quad (31)$$

The above equation assumes that the receiver has been synchronized so that $s(0), \dots, s(N_m \cdot K_m - 1)$ are samples of a probe component.

(J) The second step in the integration of the K_m probe components is to derive the signal vector $a_e(t)$:

$$a_e(t) = \sum_{i=0}^{N_m-1} a_s(t, i) \quad (32)$$

The signal vector $a_e(t)$ is the coherent integration of K_m sequence periods and is the starting point in the determination of the channel digit response, $\hat{p}(t)$. At the same time, another vector of N_m points is also calculated.

$$\hat{s}(t) = \sum_{i=0}^{N_m-1} (-1)^i a_s(t, i) \quad (33)$$

The noise vector, $\hat{s}(t)$, eliminates the signal contribution by alternating the sign in its summation, and it is the basis for the noise power measurement.

1. Channel Digit Response Measurements

(U) As mentioned above, the primary objective of the probe processing is to derive the approxi-

mate channel digit response $\hat{p}(t)$. Let $\hat{p}(t, i)$ be the sampled data representation of $\hat{p}(t)$ obtained in the i th measurement interval. From a discrete version of the derivation of Section IIa, the following result is obtained:

$$\hat{R}(t, i) = \sum_{j=0}^{N_m-1} \frac{M(j)+1}{2} a_e(t+j \cdot N_m); \quad 0 \leq i < N_m \quad (34)$$

where the index $i+j \cdot N_m$ is taken modulo N_m . The index j on $\hat{p}(t, i)$ is introduced at this point to facilitate subsequent description; it indicates that $\hat{p}(t, i)$ is derived from the i th measurement interval of K_m probe components.

(D) An oscilloscope display of the $\hat{p}(t, i)$ vector is provided, and it is updated during each measurement interval by the processor. Unfortunately, the N_m points in the display are too many to be retained during a long-term experiment; however, two useful measures of the multipath situation are recorded for evaluation of system performance.

(U) The first multipath measure is the autocorrelation of the channel digit response, $\hat{R}(t, i)$, taken at multiples of the digit length, N_m ,

$$\hat{R}_{ij}(t, iN_m) = \sum_{k=0}^{N_m-1} \hat{R}(t, j+kN_m); \quad i=0 \dots 6 \quad (35)$$

where the index $j+iN_m$ is taken modulo N_m . These measurements are indicative of the time smear of the channel, and they are important in measuring the extent of intersymbol interference. For example, if the channel were ideal (broad band) then $\hat{p}(t, j)$ and $\hat{p}(t, j+iN_m)$ would have no overlap for $j > 0$. Then $\hat{R}_{ij}(t, iN_m)$ would be zero for $j > 0$. Thus, as $\hat{R}_{ij}(t, iN_m)$ with $j > 0$ becomes large relative to $\hat{R}_{ii}(t, 0)$, the time smear of the channel increases.

(D) The second multipath measure is the cross correlation between two consecutive measurements of $\hat{p}(t, i)$. Let $\hat{p}(t-1, i), \hat{p}(t, i)$ be two digital response measurements, based on consecutive but nonoverlapping measurement intervals. Then, the normalized cross correlation coefficient, $\rho(t)$, between the two measurements at zero offset is given by

$$\rho(t) = \frac{\sum_{k=0}^{N_m-1} \hat{R}(t-1, i)\hat{R}(t, i)}{\sqrt{\hat{R}_{ii}(t-1, 0)\hat{R}_{ii}(t, 0)}} \quad (36)$$

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

The magnitude of $\alpha(t)$ is always less than one. If the serial-link channel error truly time invariant (and there were no noise), then $\alpha(t)$ would equal one. If the channel was completely unstable so that the two parameters $\beta(t) = 1, \alpha$ and $\beta(t), \alpha$ had nothing in common, then $\beta(t)$ would have a mean value of zero.

2. Measurement of Signal and Noise Powers

(U) The wideband signal and noise powers, SP and NP, are measured to allow evaluation of system performance. Let $a(i)$ be the signal contribution to the i th sample in a single received sequence period. The noise contributions $n(i)$ are assumed to be normally distributed with zero mean and variance σ_n^2 and are also assumed to be independent. Then, if the channel is stable,

$$e_t(i) = K_m \cdot K_w a(i) + \sum_{j=0}^{K_w K_m - 1} n(j \cdot N_m + i) \quad (37)$$

Then $e_t(i)$ will be of mean $K_m K_w a(i)$ and variance $K_m \cdot K_w \sigma_n^2$. The average "signal-to-noise" ratio (mean-squared-to-variance ratio) on $e_t(i)$, SNR_{ew} is then

$$\text{SNR}_{ew} = K_m K_w \sum_{i=0}^{N_m - 1} \frac{|e_t(i)|^2}{\sigma_n^2} \quad (38)$$

The constants K_m and K_w are selected at the time of system design so that the noise contribution to $e_t(i)$ can be neglected. The approximate signal power, SP, is given by

$$\begin{aligned} SP &= \sum_{i=0}^{N_m - 1} |e_t(i)|^2 \\ &= (K_m \cdot K_w)^2 \sum_{i=0}^{N_m - 1} |a(i)|^2 \end{aligned} \quad (39)$$

which is the signal energy over K_w probe measurement intervals.

(U) If the medium is stable over the measurement interval, the signal contribution to the $a(i)$ vector is zero. Thus, $a(i)$ has a zero mean and a variance $K_m \cdot K_w \sigma_a^2$. Let

$$NP = \sum_{i=0}^{N_m - 1} |a(i)|^2 \quad (41)$$

Then NP is χ^2 distributed with N_m degrees of freedom. In the systems discussed here, $N_m >> 50$ and the distribution on NP can be approximated by a Gaussian distribution with mean $N_m \cdot K_w \sigma_a^2$ and variance $2N_m \cdot K_w \cdot K_w \sigma_a^2$. The mean squared-to-variance ratio on NP is high, so NP is a good estimate of the noise power in K_w probe components.

(U) The input signal-to-noise ratio, SNR_m , is defined as

$$\text{SNR}_m = \frac{\int e_t^2(t) dt}{\int n^2(t) dt} \quad (42)$$

where the integration is carried out over the probe measurement interval. From the sampling theorem,

$$\int e_t^2(t) dt = \frac{1}{2T} \sum |e_t(i)|^2 \quad (43)$$

$$\int n^2(t) dt = \frac{1}{2T} \sum |n(i)|^2 \quad (44)$$

where the summation extends over the $N_m = N_w \cdot K_w$ samples in the probe measurement interval. Because the noise samples $n(i)$ are independent and have zero mean,

$$E \left[\int e_t^2(t) dt \right] = \frac{1}{2T} N_m \cdot K_w \cdot K_m \cdot K_w \sigma_a^2 \quad (45)$$

$$= \frac{1}{2T} (NP) \quad (46)$$

$$\begin{aligned} E \left[\int n^2(t) dt \right] &= \frac{1}{2T} \sum |n(i)|^2 = \frac{1}{2T} K_m \cdot K_w \sum_{i=0}^{N_m - 1} |n(i)|^2 \\ &= \frac{1}{2T} K_m \cdot K_w \quad (47) \end{aligned}$$

Substituting Eqs. (46) and (48) into Eq. (42) gives

$$\text{SNR}_m = \frac{1}{K_m \cdot K_w} \left(\frac{NP}{SP} \right) \quad (48)$$

Thus, the input signal-to-noise ratio can be determined from the probe measurements of SP and NP. Although this measurement is determined from the probe portion of the measurement

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

interval, it is also applicable to the information component by the assumed invariance of the noise.

c. INFORMATION CONTEXT PROCESSING

(c) (i) The objective of the information component processing is to make coherent decisions on the transmitted symbol values. These decisions can be stored against known answers in the case of a particular transmission. For demonstration purposes, the received values can be printed as characters on a Teletype. In either situation, decisions are made on the basis of thresholds on the output of a matched filter.

(c) (ii) The first step in the processing of the k th information component is to form a coherent average $a_t(k, i)$ of the information component:

$$a_t(k, i) = \sum_{j=0}^{N_s-1} d(jk+i) K_m \cdot N_s + jN_s + i \quad (30)$$

This yields a vector of N_s points and is analogous to the computation of the $a_t(k, i)$ vector in the probe processing. The $a_t(k, i)$ vector contains K_m information symbols, each composed of K_m digits in a prescribed order. For the 115 and 116 experiments, $K_m = 3$ and $K_m = 5$, respectively.

(c) (iii) To match filter $s_t(k, j)$, a cross correlation is performed of $a_t(k, i)$ with $p(k, j)$, where $p(k, j)$ is the digit response found in the previous measurement interval, k . The decision process requires samples of the matched-filter output taken at intervals of one digit length, N_s , apart. Thus, only K_m cross correlations are needed to provide the required data from $a_t(k, i)$. Specifically, let

$$L'(k, j) = \sum_{i=0}^{N_s-1} K_i + jN_s a_t(k, i), \quad 0 \leq j < K_m \quad (51)$$

$$L(k, j) = \sum_{i=0}^{N_s-1} a_t(k, i) L'(k, j - K_m + i) \quad (52)$$

where the index $i+jN_s$ is taken modulo N_s . The values $L'(k, j)$ represent a cross correlation of $a_t(k, i)$ with $p(k, j)$ displaced by multiples of N_s samples, or equivalently, T_s sec. Note that the cross correlation is performed in a circular manner. (c) (iv) To determine the symbol values, a zero threshold is applied to the symbol matched-filter

(c) (v) A natural question arising from Eq. (51) is concerned with how much synchronization is required for the values $L'(k, i)$ to be taken at exactly the correct sampling time. The answer is that no *fine-grain synchronization* is required. If the $a_t(k, i)$ vector contains primarily the information component (and consequently the $a_t(k, i)$ vector contains primarily the probe component), as previously assumed, then $L'(k, i)$ is always taken at exactly the correct time. The reason for this is that the transmissor provides a fixed time offset between the probe and information digits. This time offset is completely preserved in both sections of the processor. Thus, if probe digit A is separated from information digit B by n digits in the transmission, they will be separated by exactly n (mod K_m) digits in the $a_t(k, i)$ and $a_t(k, j)$ vectors.

(c) (vi) The values $L'(k, i)$ are the response of a filter matched to each of the symbols must be obtained. Since the information symbols are formed from known combinations of digits, the symbol filter responses can be found from combinations of the $L'(k, i)$.

(c) (vii) Specifically, suppose that the j th symbol in the information component is as given in Eq. (19). Then output of the matched filter for the j th symbol in the k th frame, $L(k, j)$, is given by

$$L(k, j) = \sum_{i=0}^{N_s-1} a_t(k, i) \sum_{m=0}^{K_m-1} K_m (i - K_m + m) N_s + m p(k, m) \quad (53)$$

where the index $(i - K_m + m) N_s + m$ is again taken modulo N_s . The summation over m in the above equation is simply $L'(k, j - K_m + i)$, so the following result is obtained:

$$L(k, j) = \sum_{i=0}^{N_s-1} a_t(k, i) L'(k, j - K_m + i) \quad (54)$$

Because the above equation is easily implemented, the use of variable symbol modulation places very little additional burden on the receiver processing.

(c) (viii) To determine the symbol values, a zero threshold is applied to the symbol matched-filter

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

outputs $L(k,i)$. If the filter output $L(k,i)$ is greater than zero, the decision $M(k,K_0+i)$ on the i th symbol in the k th information component is 1. Otherwise the decision is -1. In the 315 and 316 systems $K_0=5$, so each information component yielded five bit decisions. These bit decisions were printed as a single five-bit Teletype character during text transmission.

(c) (2) More elaborate decision techniques can be applied to reduce the effects of intersymbol interference. In the 315 and 316 systems, the choice of symbol durations was such that intersymbol interference was negligible, and these techniques were not required.

3. Setting of Receiver Decisions

(1) To evaluate the system error performance, the receiver decisions $d(i)$ are stored against known symbol values in the information component one known, as they are in the case of a periodic transmission. The error count on the information components for the periodic transmission is denoted E_i and is one of the parameters computed for every K_m probe components.

(c) (2) If information unknown to the receiver is being transmitted, it is of course not possible to score the information component. A completely adequate measure of system performance can be obtained, however, by performing the decision process on the vector $a_t(k,i)$ in a manner identical to that performed on $a_t(K_0)$. Since the digits in the probe have a fixed interpretation in terms of symbols, scoring of the probe component is always possible, since it is independent of the information being transmitted. The error count on the probe component is designated E_p .

(c) (3) When a periodic transmission is sent, the expected values of the two error counts E_i and E_p should be the same, as the $a_t(k,i)$ and $a_t(K_0)$ vectors are statistically the same. On the other hand, when text is transmitted, E_i depends on the particular text transmitted, and it is not a measure of system error performance.

B. SYNCHRONIZATION

(c) (2) In the preceding discussion, synchronization between the receiver and received signal has been assumed. When a periodic transmission is sent, the probe and information components are

identical and no synchronization is necessary. On the other hand, when text is transmitted, synchronization is required to ensure that each character is presented in the correct sequence. (c) (2) For a practical communication system, synchronization must be performed automatically and checked continuously. The system considered here, however, was intended primarily to determine the feasibility of the coherent integrated matched-filter technique. Consequently, very little effort was expended on the synchronization problem. Indeed, during all of the performance measurement experiments a periodic transmission was carried out to eliminate the problem entirely. The following manual synchronization procedure was used whenever required for the actual transmission of text.

(c) (2) Synchronization is achieved by interaction between an operator observing the oscilloscope display of $j(k,i)$ and the processor. The operator can delay the processor time base for an integer number of digit durations by typing an appropriate command. Two steps are required to achieve synchronization with different transmission being required for each step.

(c) (2) The first step requires the basic periodic transmission. The operator observes the display of $j(k,i)$ and causes sufficient delays to locate the digit response in the center of the display. This locates the junction between the probe and information components to be within an integer number of sequence periods.

(c) (2) During the second step, a transmission with a constant carrier in each information component is used. If the receiver is properly synchronized, the channel digit response is a clean pulse, with zero levels to either side. If the receiver is not properly synchronized, then the $a_t(k,i)$ vectors contain the carrier as well as the response, and the display of the digit response has a distinctive notches appearance. The operator delays the processor by multiples of T_m until the proper display is obtained.

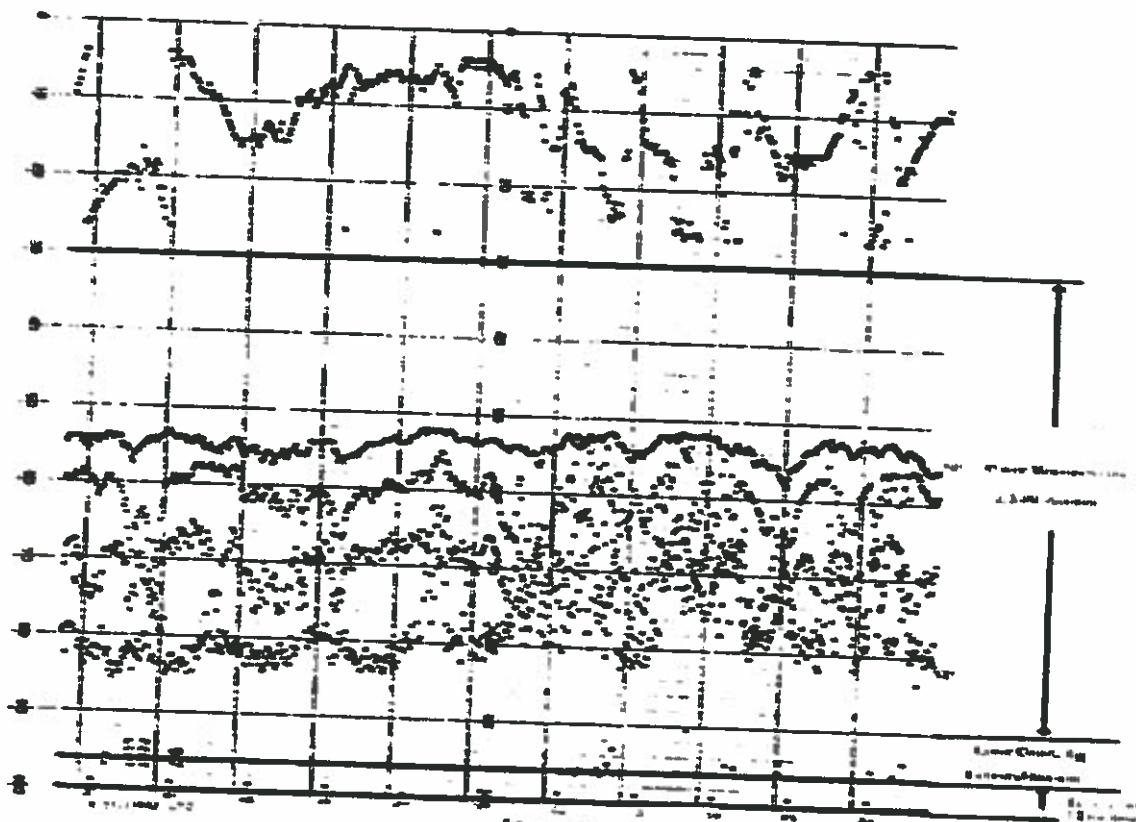

Figure 5. Typical multipoint plot from the M5 and M6 systems. (Figure unclassified.)

nization at lower signal-to-noise ratios is more difficult, but it can be done by an experienced operator.

B. IMPLEMENTATION

(U) The receiver processing for both communication systems was performed by small, general purpose, digital computers, frequently called minicomputers. The M5 systems were implemented on a Digital Equipment Corporation LINC-8 computer with a 4,096-word (12 bits/word) memory. The M6 systems were implemented on a DEC PDP-8E system with an 8,192 word (12 bits/word) memory.

(S) Both machines contained a hardware multiply capability. Such a feature is required if the system is to perform the matched filtering in real time. If it is assumed that both the information and probe components are match-filtered to receive

the information and score the probe component, the number of multiplications, n_{mult} , required for either component is

$$n_{mult} = N_m \frac{\text{multiples}}{\text{matched filter}} \times K_m \frac{\text{digits}}{\text{component}} \quad (54)$$

The time, T_{mult} , for a component is

$$T_{mult} = K_m \cdot N_m \frac{K_m}{f_{cm}} \quad (55)$$

Thus, the multiplication rate, R_{mult} , required is

$$R_{mult} = \frac{n_{mult}}{T_{mult}} \quad (56)$$

$$= \frac{K_m \cdot f_{cm}}{K_m \cdot K_m} \quad (57)$$

$$= 788 \text{ multiplications/sec} \quad (58)$$

UNCLASSIFIED

UNCLASSIFIED

for typical MS and M6 experimental parameters. This rate is easily matched with most modern microcomputers; however, the multiplication rate must nevertheless be considered in system parameter design.

(U) The primary output of the processor is digital magnetic tape—specifically, LINC format tape. The probe measurements and error counts are stored in blocks, with date from seven measurement intervals and time information in each block. Our tape is filed every 6 or 7 days. Every time a tape block is written, its entry is typed into a Teletype log for reference purposes. A secondary, but important, output is given as a multipoint plotter controlled by the processor. This plot gives the values of S/N and N/P on a minute-by-minute basis. The probe error count, F_{err} , is also plotted, along with a timing track. Figure 5 depicts a typical multipoint plot and the associated scale factors.

IV. EXPERIMENTAL PROGRAM

(U) Five long-term experiments (MSA, M6B, M6A, M6C, and M6D) were performed between fixed sites in the Straits of Florida to evaluate the effectiveness of coherent interpretation/matched-filter techniques. The dates and durations for each of these experiments are shown in Table I. A total of 4,554 hours (100 days) of valid data was obtained and analyzed over either 7- or 42-mile distance. Section IVa describes the differences among the five experiments. Section IVb describes the experimental results.

A. DIFFERENCES AMONG EXPERIMENTS

(U) In each of the five experiments, the transmission was generated by the source off Poverty Rocks Light. During the M5 experiment, signals were received at a hydrophone located 7 miles from the Poverty Rocks source, while in the M6 experiments, signals were received at the Bimini hydrophone, 42 miles from the source. Each experiment had more than one part, as indicated by the third letter in the experiment identification; for example, M6C was the third part of the M6 experiment. The purpose of each part of both experiments is described below.

(U) Reference 4 describes the first-site range in detail.

(U) The M5 experiment had two parts, each having distinctly different purposes. The objective of the MSA experiment was to measure the communication system performance at low signal-to-noise ratios. Consequently, the transmitter power was reduced to give an average signal-to-noise ratio of 0 db. The resulting low signal-to-noise ratios increased the variance on the transmission measurements. After completion of the MSA portion, the signal power was increased for the second part of the M5 experiment to improve the quality of the transmission measurements. Because of the high input signal-to-noise ratios in the M6B experiment, the error rate was reduced to a point where system error performance could not be evaluated.

(U) The M6 experiment had three parts, each representing a different choice of system parameters. In the M6A experiment, the same transmission format was used as in the M5 experiment so as to obtain comparison data over the two distances. The sequence duration in this first experiment was known to be too short for reliable operation at the 42-mile range. Further, the average signal-to-noise ratios at Bimini were lower than expected, because of inadequate source drive at Poverty Rocks. Consequently, a second experiment, M6B, with extremely high noise and multipath resistance (and low data rate) was initiated. Results from the M6B experiment indicated that its design was too conservative and that a compromise between the M6A and M6C parameters was in order. Subsequently, the third

experimental, MEC, was implemented as an optoelectronic system for the 42-mm distance.

(U) The five experiments have very similar transmission formats; indeed, the only major difference among the experiments is in the digit structure and duration. Table 2 depicts the parameters that were common to all experiments, but later paragraphs will point out the differences among the remaining system parameters. Because of the common features of the experiments and the software implementation of the processor, the transition from one experiment to the next was easily accomplished.

(U) Although five different experiments were performed, there are only three different sets of system parameters, with the MSA, MGB, and MCA experiments all employing the same transmission formats. Table 3 gives the significant differences among the experiments.

(U) The primary difference between the MSA, MGB, and MCA format and the MGB and MEC format is in the digit duration and structure, with a digit in the MGB system being 1.5 times

bigger than a digit in the MSA system and a digit in the MEC system being 1.8 times longer than a digit in the MSA system. The purpose of the digit lengthening in the MGB and MEC systems was to increase the symbol processing gains and improve the performance against multipath.

(U) Of the last two systems, MGB and MEC, the MGB has the highest processing gains and, correspondingly, the lowest transmission rate. The MEC is exactly twice as fast and has 3 db less processing gain than the MGB system. Thus, the MEC system can be considered a compromise between the short digit durations of the MSA format and the very long durations of the MGB format.

(U) Both the MGB and the MEC systems employed broadband coding of the digit waveform to avoid the reduction of symbol bandwidth with the increase in symbol duration. This was necessary to retain the advantages of a broadband transmission against noise and multipath when the symbol duration is long relative to the digit bandwidth. A comparison of the digit spectra for

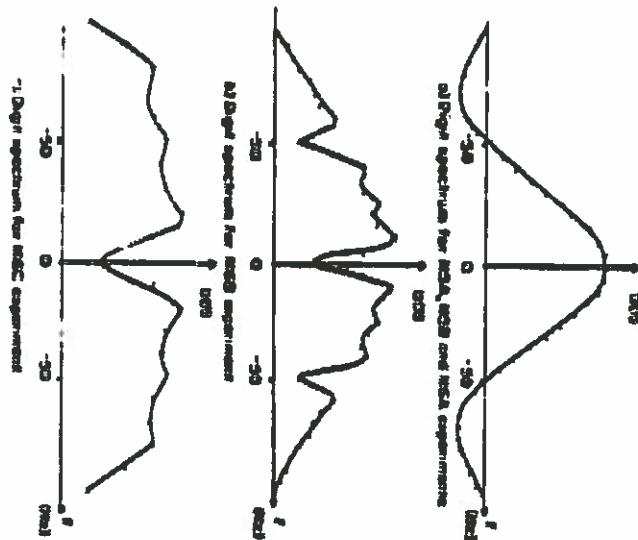

Figure 6. Comparison of digit spectra. (Figure unclassified)

The three formats is shown in Figure 6. Because of the filtering of the source and reflector and the receiver analog filter, only the spectral components in a 100-hz band about the center are important.

a. EXPERIMENTAL RESULTS

(U) The five experiments yielded data on both acoustic transmission conditions and system error performance. In this section, only measurements that bear on the evaluation of system error performance or on future applications on the communication systems are discussed. The remaining acoustic transmission measurements have been made available to other scientists, and they may be reported later.

b. Signal-to-Noise Ratio Histograms

(U) To interpret the communication performance data, an understanding of the signal and noise environment of each experiment is necessary. Figures 7 and 8 depict histograms of the sideband received signal-to-noise ratio, SNR_o, with ordinate axis of both frequency in percent and time in hours. The abscissa represents SNR_o averaged over the time interval shown in Table 3, and it

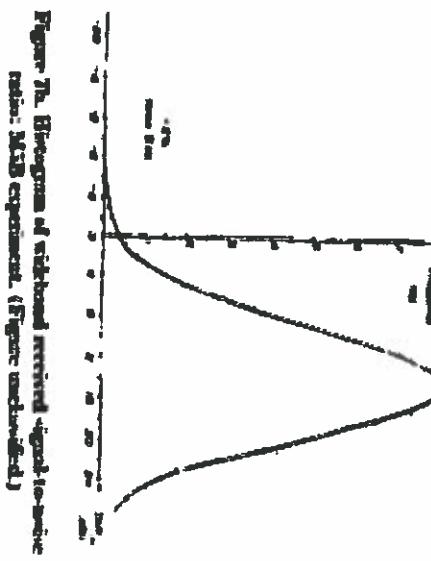

Figure 7a. Histogram of withdrawn received signal-to-noise ratio. NSB experiment. (Figure unclassified)

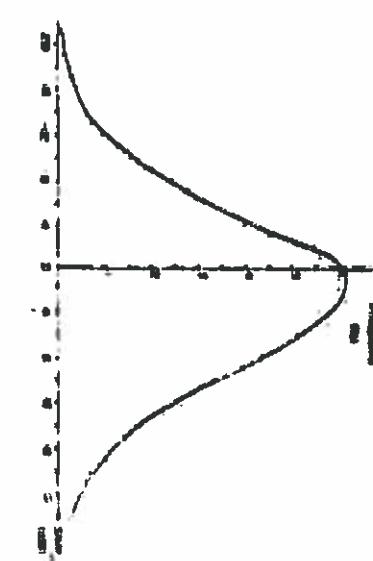

Figure 7b. Histogram of withdrawn received signal-to-noise ratio. NSC experiment. (Figure unclassified)

is quantized in 1-dB-wide bins. Because the source level was not held constant during the experiments, these histograms reflect only the signal-to-noise ratio environment as seen by the receiver, not a general measurement of receiver propagation. Nevertheless, they indicate the extent of data available at a given input signal-to-noise ratio, so the statistical significance of the error measurements can be understood.

(C) Figure 7 gives the signal-to-noise ratio histograms for the two phases of the NS series of experiments. As mentioned earlier, the source levels for the NSB experiment were deliberately reduced to achieve the low average signal-to-noise ratios shown in Fig. 7a. Consequently, a large amount of data with reasonably frequent

UNCLASSIFIED

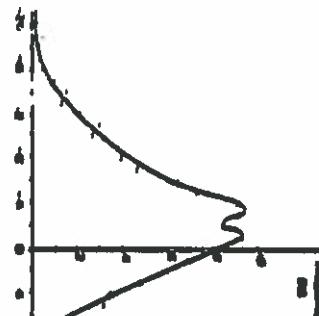

Figure 5a. Histogram of withheld received signal-to-noise ratio: MSA experiment. (Figure unclassified)

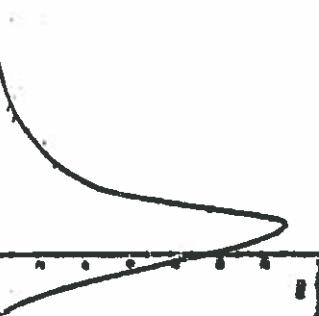

Figure 5b. Histogram of withheld received signal-to-noise ratio: MEC experiment. (Figure unclassified)

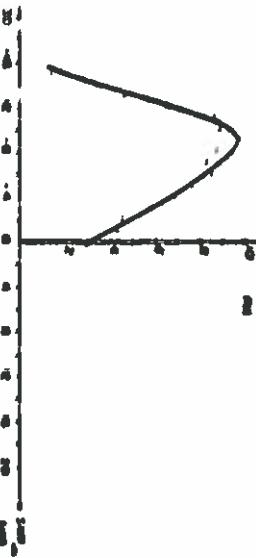

Figure 5c. Histogram of withheld received signal-to-noise ratio: MSB experiment. (Figure unclassified)

Figure 7b gives the corresponding histogram for the MSB experiment, in which the source was driven at maximum available levels, yielding about a 12-dB increase in mean SNR_m over that of the MSA experiment. Because only 1.2 percent of the MSB data correspond to SNR_m below 0 dB, the error performance data for the MSB experiment were not statistically significant and were not processed further. Thus, the MSB experiment does not appear in the subsequent presentation of the error performance data.

(U) Figure 8 gives the SNR_m histograms for the three M6 series experiments. The M6A experiment was operated at signal-to-noise ratios that were only slightly (6 dB) worse than those of the M5A experiment, so an adequate measurement of system performance could be achieved. Because of failure in an amplifier driving the Fourier Banks source, very low signal-to-noise ratios were available for the M6B experiment, as shown in Fig. 8b.

These low signal-to-noise ratios motivated the choice of system parameters for the M6B experiment. Later, a new amplifier was installed at Fourier Banks, which improved the signal-to-noise ratio situation at Bonnini, and the M6C experiment was initiated. As shown in Fig. 8c, the M6C experiment experienced about the same SNR_m environment as the M5A experiment had experienced earlier.

2. Communication System Performance

(U) Evaluation of communication system performance is a difficult problem when one is confronted with the varying conditions of the acoustic medium. The technique described here is based on a well-known theoretical model, and it offers several advantages in terms of clarity and convenience.

(U) The primary data for the performance measurements consist of input signal-to-noise ratio averages and the cumulative error count $E = E_p + E_t$ taken over the averaging interval. Table 4 gives the averaging times and corresponding number of bit decisions for each experiment. Because the number of bit decisions is known, a probability of error for each data pair can be computed. A natural question arises as to the best way of presenting the relationship between average input signal-to-noise ratio and probability of error when thousands of such pairs are available.

(U) One method of evaluating the system performance would be to sum all of the error counts, E_i , for a fixed average signal-to-noise ratio and

CONFIDENTIAL

2.0	10.5	2.0

then divide by the total number of bit decisions involved to obtain a probability of error. The disadvantage of this technique is that it does not indicate the variations in system error performance over time. To depict such variations, the error performance of each block is evaluated, with the results placed in histogram form to indicate the frequency of occurrence.

(U) A histogram of error probabilities would satisfy the above requirement; however, the non-uniformity of the probability scale makes the histogram difficult to understand. To overcome this problem, a conversion of the measured probability of error to a more uniform axis is helpful. A particularly helpful conversion from a systems analysis standpoint is to go from probability of error to output signal-to-noise ratio, which can be presented in decibels.

(U) Several alternatives exist for converting from error probability to output signal-to-noise ratio, but the simplest technique is to use a known relation from an existing theoretical model. In this paper, the conversion of probability of error to output signal-to-noise ratio is based on the theoretical results for the likelihood ratio receiver for a known linear, time-invariant channel with added white Gaussian noise. For this receiver, the probability of error, P_{e} , is given by

$$P_{\text{e}} = \Phi(-1/D) \quad (59)$$

where

$$\Phi(x) = \int_{-\infty}^x (e^{-z^2/2}) dz \quad (60)$$

and D is the output signal-to-noise ratio. For this situation, the conversion of error probability to output signal-to-noise ratio can be accomplished by solving Eq. (60) for D . That is

$$D = \Phi^{-1}(P_{\text{e}}) \quad (61)$$

where $\Phi^{-1}(x)$ is the inverse of the function $\Phi(x)$ defined in Eq. (60). In the tabular section of

CONFIDENTIAL

UNCLASSIFIED

UNCLASSIFIED
CONFIDENTIAL

Figure 10. Histogram of values of D vs. $\text{SNR}_m = 10 \text{ db}$.
(Figure made--HdL)

the model, D is in fact the mean-squared-in-variance ratio of the matched-filter output. The motivation for the above choice of theoretical model comes from both its agreement with the assumed conditions of the real acoustic channel and its ease of use.

(U) The analysis technique from this point is straightforward. The error probability for each block of data is converted to output signal-to-noise ratio D in decibels through Eq. (61). Then, histograms of the resulting values of D are plotted for each signal-to-noise ratio. This provides a smooth and easily understood histogram, as shown in Fig. 9.

(U) One disadvantage of the histogram of output signal-to-noise ratios, D , is that the smallest

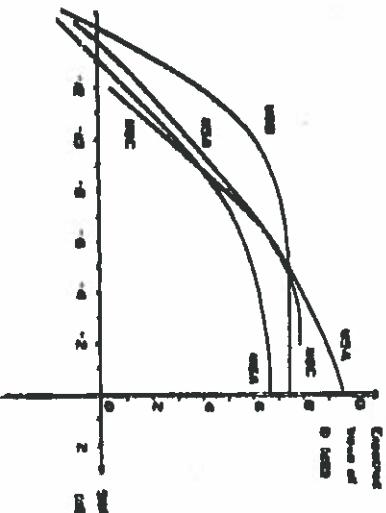

Figure 11. Standard deviation of D vs. SNR_m . (Figure dashed C-finite)

measurable probability of error is about 0.001, which results from the fact that only one or two thousand bit decisions are made in each block. Such a probability of error corresponds to a value of D of about 11 db, so the histograms are necessarily truncated at that value.

(U) Figure 10 depicts the means of the output signal-to-noise histograms for the four communication experiments. (MSB is omitted, because of its excessive signal-to-noise ratios). Points are shown on this plot only if at least 10,000 bit decisions were made at the given SNR_m . Consequently, each point shown is a statistically significant measure of the system performance. Figure 11 depicts the standard deviations of the same histograms.

(U) Note that there is a distinctive leveling off of output signal-to-noise ratio with increasing input signal-to-noise ratio. This is most likely due to the non-Gaussian nature of the noise, which becomes significant at higher signal-to-noise ratios. Also worthy of note is the fact that probabilities of error of 0.01 are achieved at input signal-to-noise ratios well below 0 db. Thus, a satisfactory system can be made to operate with SNR_m below 0 db. The leveling off of the 16B curve is probably due to the very long reference determination time involved (128 sec).

(U) Yet another way of interpreting communication system performance is to compare the experimental system performance with that of the idealized system described previously. For the

UNCLASSIFIED

CONFIDENTIAL

Ideal system, the output signal-to-noise ratio D is given by

$$D_{\text{ideal}} = 2\pi T K_a \cdot E_a \cdot \text{SNR}_a \quad (62)$$

At a fixed SNR_a , the difference, Δ , between D_{ideal} and D can be found to indicate relative system performance:

$$\frac{D - D_{\text{ideal}}}{D} \quad (63)$$

This has the advantage of placing systems with different transmission rates on the same basis.

For example, the MEB system is better than the MCC system in absolute performance, because of its slower transmission rate. When compared relative to the ideal system with the same rate, however, the relative performance of the MCC system is better. This is shown in Fig. 12 for the four systems.

(c) Of the four systems shown in Fig. 11 the MSA system has the best relative performance, while MEB has the worst relative performance. This is probably because of the increased stability of the 7-mm path with a 73-sec probe measurement interval over the 42-mm path with a 128-sec probe measurement interval. Similarly, the relative performance of the MSA and MCC systems is worse than that of the MSA system strictly because of range. The relative performance difference between the MSA and MCC systems shown in Fig. 12 is not considered to be significant.

(c) In summary, the performance of the communication systems was very well established with large amounts of data. With careful choice of system parameters, a coherent matched-filter communications system such as MEF can yield error probabilities of 0.01 at input signal-to-noise ratios of -10 dB. Such a system would be operating with a performance only 6 db worse than that of an idealized system.

J. Channel Stability Measurements

(c) The utility of the matched-filter technique studied here is highly dependent on the stability of the channel. If the acoustic channel changes significantly from the time of the probe measurement to the time of the information component processing, then the filter will not be properly

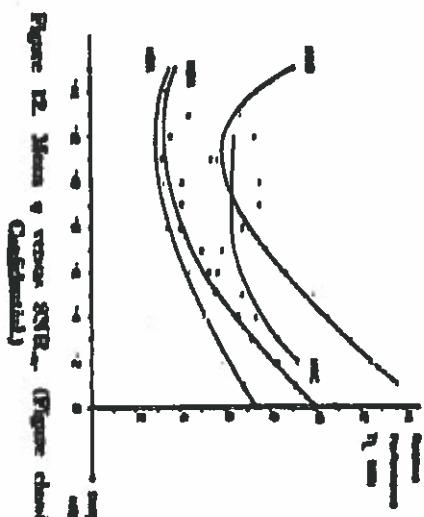

Figure 12. Mean Δ versus SNR. (Figure classified)

matched and an increase in errors can be expected. On the other hand, if the acoustic medium is very stable, then the integration time of the probe component can be increased to improve the measurement of the channel digit response.

(U) Because of the importance of the channel stability to future applications, the five experiments indicated in elementary measurement of the wideband channel stability, specifically, the normalized cross correlation coefficient $\rho(t)$ described in Section IIIa. Although correlation coefficient data are available for the full duration of each experiment, only a few days of such data for each experiment have been analyzed. These days were chosen from continuous, high-quality data to determine any daily fluctuations. Only data with SNR_a greater than 10 db were considered.

(U) The most convenient way to understand the variations of the acoustic channel is to construct histograms of the correlation coefficient. Figure 13 depicts histograms of $\rho(t)$ for the MSA, MSA, and MEB experiments. The histograms represent one-day intervals (about 1,440 correlation values per histogram) with a bin size of 0.01. Note that the abscissa on each plot begins at 0.5, not zero. Since MSA and MSA used the same transmission parameters, the decrease in mean value can be attributed to the increased distance, 42 mm instead of 7 mm.

(U) Figures 13a and 13c depict the $\rho(t)$ histograms for the MSA and MEB experiments. The obvious widening of the MEB histograms is due to the

UNCLASSIFIED

UNCLASSIFIED

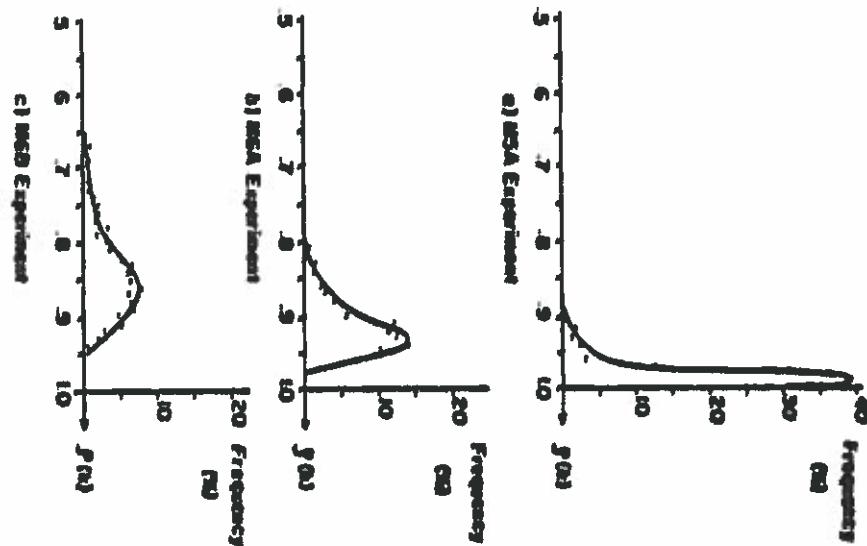

Figure 11. Histograms of PSD. (Figure unlabelled)

increased measurement interval duration, 128 sec instead of 73 sec. The lower correlation values of the digit response indicate that the measurement of the digit response is less accurate in the MGB system than in the MSA system. This offers at least a partial explanation for the poor relative performance of the MGB system shown in Figure 12. The correlation function histograms for the MSA and MGB experiments are nearly identical, as the distance and integration times are similar for the two experiments. Also, the histograms for the MSA and MGB experiments are similar.

V. SPATIAL STABILITY MEASUREMENTS

(U) The preceding sections described the operation and performance of an underwater acoustic communication system operating between two

fixed points. In a practical submarine communication system, one or both ends of the acoustic channel is in motion, so spatial variations as well as temporal variations are important. This section describes two measurements of the spatial stability of the medium and provides the foundation for the extension of the fixed-site communication techniques previously discussed to the submarine communication problem.

(U) The fixed-site experiments have shown the temporal stability of the medium to be sufficient to allow integration times of the order of one minute. From a purely geometric point of view, the medium should also be stable under spatial displacements that are common to submarine platforms. For example, a submarine on a 10-foot, zero Doppler track at a range of 100 nmi subtends less than 0.1 deg of arc in one minute. The wide-band characteristics of the acoustic channel would not be expected to change significantly under such a displacement. Nevertheless, careful measurements have been made to validate this intuitive understanding.

(U) Two measurement techniques were employed to study the spatial stability of the acoustic channel. The first used coherent cross correlation of received waveforms without any coherent integration, and it yielded anomalous results. The second technique used coherent cross correlation with 12.4 dB of coherent integration, and this produced consistent results. In the following sections, each measurement technique is described in detail, and an explanation of the differences in their results is offered.

A. COHERENT CROSS CORRELATION WITHOUT COHERENT INTEGRATION

(U) In this measurement technique, the spatial stability of the medium was measured in terms of normalized correlation coefficients, $R^*(\tau)$, analogous to the correlation coefficient, $r(k)$, studied in the MS and MG experiments. Because of the presence of the Doppler effect, however, the definition had to be modified slightly.

(U) The transmission was a 15-bit, pseudo-random sequence similar to that of the MSA, MGB, and MGA experiments. The sequence was scaled from the previous carrier frequency of 420 Hz to a center frequency of 120 Hz, to be con-

UNCLASSIFIED

-CONTINUEE

UNCLASSIFIED

CONFIDENTIAL

possible with the acoustic source. The resulting sequence has a period T_m of 343 msec and a zero-to-zero bandwidth of 87.5 Hz, and it was transmitted continuously from the towed source during each experiment.

(U) Let $s_i(t)$ be the received signal, bandpass filtered in a 100-Hz band centered on the carrier frequency of 250 Hz. Consider a segment of $s_i(t)$ of duration T_m that contains an integer number of sequence periods at zero Doppler, that is, $T_m = kT_s$ for some integer k . The normalized cross correlation function $\alpha(i)$ of this segment with the input $s_i(t)$ is given by

$$\alpha(i) = \sqrt{\int_{t_0}^{t_0+T_m} s_i(t)s_i^*(t+i\Delta t)} \quad (64)$$

where t_0 is the starting time of the selected segment. Note that, in general, $\alpha(i)$ is complex valued. If there is no Doppler and the medium is perfectly stable, then $\alpha(i)$ will be periodic, with the same period as the sequence, and it will attain a maximum value of unity. If there is no Doppler, but the medium is changing, values of $\alpha(i)$ taken at multiples of the sequence period are a measure of the stability of the channel. Consequently, the correlation function evaluated at multiples of the segment duration $\alpha(iT_m)$, $i=1, 2, \dots$, will also be an indication of channel stability.

(U) Since $s_i(t)$ was generated by a moving source, the effects of Doppler will be present, even on a nominal "zero Doppler" track. A convenient approach to understanding the effects of Doppler is to consider it as producing either a time compression or expansion of the received signal. Let T_m' be the duration of a segment of $s_i(t)$ at zero Doppler and let T_m'' be the duration of the same segment as received from the source approaching the hydrophone at a velocity c . Then

$$T_m' = (1 - \alpha c) T_m \quad (65)$$

where c is the average speed of sound in the same medium as c . If the source is approaching the receiver at 10 knots, T_m' is reduced by 0.14 percent. Similarly, if the source is leaving the receiver at 10 knots, T_m' will be increased by 0.14 percent. Although the percent variation may appear to be

small, the rate-averages of such time-axis distortions are significant when coherent techniques are employed.

(U) If the velocity of the source and the average sound velocity were known, the normalized correlation function of Eq. (64) could be evaluated at multiples of the Doppler-dispersed sequence duration, T_m'' . Unfortunately, neither variable is sufficiently well determined to calculate T_m'' adequately. In the September 1974 experiments, a new correlation coefficient, $\alpha''(i)$, was defined so as to alleviate the effects of Doppler. Let,

$$\alpha''(i) = \max [|\alpha(iT_m''(1 - \epsilon))|; -i \leq \epsilon \leq +1] \quad (66)$$

where $i = 1, \dots, 7$.

$$1 - \frac{|\epsilon|}{c_m} \quad (67)$$

ϵ is the largest anticipated Doppler rate and c_m is an estimate of the average speed of sound. The purpose of selecting the maximum magnitude of $\alpha(i)$ in an interval is to ensure that the correlation coefficient corresponds to the correlation value at correct time alignment in the presence of Doppler.

(U) Two important differences between the correlation coefficient $\alpha(k)$ of the M5 and M6 experiments and the correlation coefficients $\alpha''(i)$ of the September 1974 experiment must be noted. First, in the M5 and M6 experiments, $\alpha(k)$ was derived from a cross correlation of two coherently integrated waveforms $s_i(t)$, $s_i(t-k)$ in Eq. (68) [whereas $\alpha''(i)$ is derived from a cross correlation of two unIntegrated input waveforms, $s_i(t)$, $s_i(t-i)$ in Eq. (64)]. Consequently, the coefficients $\alpha''(i)$ are much more sensitive to both noise and short-term channel variations than the coefficient $\alpha(k)$ measured previously.

(U) The second important difference between the measurement of $\alpha''(i)$ in the September 1974 experiment and the measurement of $\alpha(k)$ in the M5 and M6 experiments is that $\alpha''(i)$ is insensitive to pure time shifts in the medium. That is, $\alpha''(i)$ can be close to unity for a medium exhibiting rapid changes in time delay because of the transmission induced in the definition of $\alpha''(i)$. Fortunately, many previous transmission measurements have shown that such changes do not exist in the ocean acoustic medium.

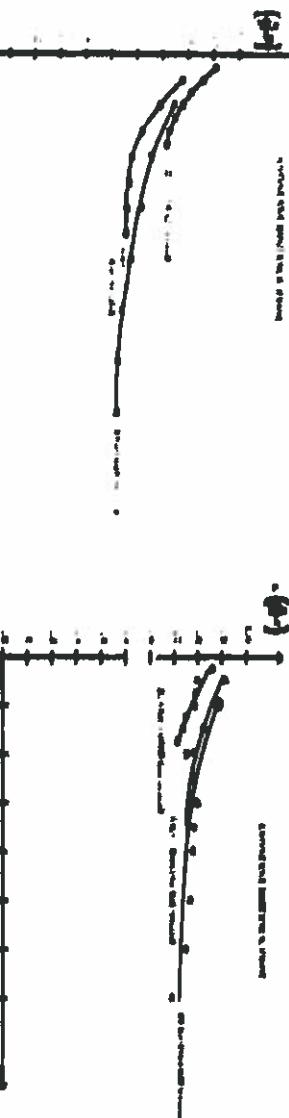

Figure 15a. Average correlation coefficients versus spatial displacement, Sept. 14, 1973. (Figure omitted)

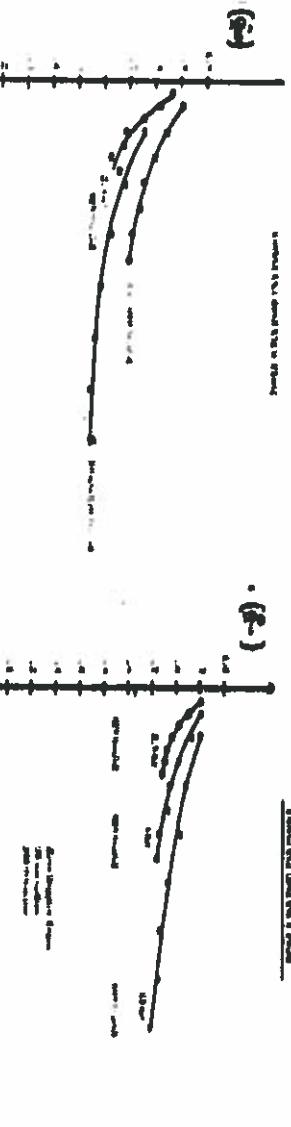

Figure 15b. Average of average correlation coefficients versus spatial displacement. (Figure omitted)

(U) The preliminary spatial stability measurements were conducted with a towed RX30 source in the Straits of Florida during September 1973. Figure 14 depicts the vessel track during these experiments. The source was towed at approximately 200-ft depth with vessel speeds of 2.5, 5, and 10 knots. Signals from the source were received at a hydrophone approximately 7 mi from the Fowey Rocks Light and were sent via cables to the laboratory on shore.

(U) Figure 15 depicts the average correlation coefficients obtained during three experiments in September 1973. Here $T_{\text{sp}}=5$ sec and i ranges from 1 to 7, corresponding to a 40-sec maximum extent. The coefficients $A^*(i)$ are plotted as a function of distance, not time, so as to indicate the stability for a fixed spatial displacement.

UNCLASSIFIED

CONFIDENTIAL

independent of source velocity. Because only 49 sets of data could be processed, the spatial variations are measured over shorter displacements for lower source velocities. Data for which $A^*(i) < 0.5$ have been eliminated from the plot, as such a value is indicative of an inadequate signal-to-noise ratio.

(U) The data given in Fig. 15 exhibit several obvious anomalies. First, the values of the correlation coefficients do not agree for the same spatial displacement. If these correlation coefficients actually measured the spatial variation of the medium, coefficients corresponding to the same spatial displacement should be equal, which is not the case. Second, on different days the relative positions of the curves for different sources are displaced. For example, on September 14, the 2.5-knot data were the most stable, whereas on September 21 and 25 the 2.5-knot data were the

UNCLASSIFIED

CONFIDENTIAL

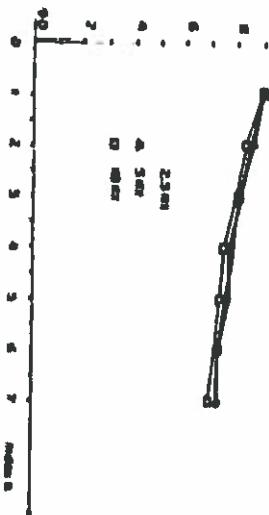

Figure 17. Average of average correlation coefficients versus time displacement. (From unclassified)

level stable. Similarly, the relative positions of the 5- and 10-knot runs change from one day to the other.

(U) Figure 16 gives the average of the results depicted in Figs. 15a, 15b, and 15c. As in the case-day plots, the correlation coefficients do not appear to depend on spatial displacement. Further, the correlation coefficients are smaller for low source speeds than for higher source speeds. Neither result agrees with common sense.

(U) In Fig. 17 the average correlation coefficients of Fig. 16 are plotted as a function of time displacement instead of spatial displacement. The close agreement between the curves for different source speeds is apparent. This indicates that the correlation coefficients, $R^{(i)}$, are dependent on time displacement, not spatial displacement as originally intended. Also, the time stability is drastically reduced from the values obtained in the extensive fixed-site experiments (15 and 16), where correlation coefficients of 0.9 were obtained over longer intervals (73 and 64 sec).

(U) Because of the above anomalies in the data, a search for possible explanations was initiated. A brief study was made of a 74 transmissons from the fixed source to determine any peculiarities in the source motion. This study showed that variations of the source about its intended linear track were insignificant.

(U) The most probable cause of the anomalies in the data are noise and surface modulation. Although the signal/noise ratios during each

experiment was estimated to be in excess of 10 db, no quantitative measurement such as that in the 15 and 16 experiments was available. Because no coherent integration was used, the correlation coefficients, $R^{(i)}$, are particularly sensitive to noise. Although previous measurements in the Straits have indicated that the extent of surface modulation is insufficient by itself to account for the observed results, surface modulation would also reduce the values of the correlation coefficients. Both of these effects are independent of spatial displacement, and they vary in extent on a day-by-day basis, which is in agreement with the data obtained.

(U) Although the experiments described in this section were unsuccessful in measuring the spatial stability of the medium, the lesson learned is important. That lesson shows the importance of coherent coherent integration in the measurement of medium stability, so the effects of noise and surface modulation do not influence the stability measurement. As a result of the September 1973 experiment, a broad measurement technique employing coherent integration was developed, and this yielded a valid measurement of spatial stability.

a. COHERENT CROSS CORRELATION WITH COHERENT INTEGRATION

(U) After the preliminary spatial stability measurements in September 1973, development of a measurement technique including coherent integration was initiated. The requirement for coherent integration was based on two considerations. First, the September 1973 experiments showed that noise and surface modulation precluded measurement of the spatial stability when no coherent integration was used; and second, an opportunity to study spatial stability at long ranges in the deep ocean was available. The input signal-to-noise ratio at these ranges required coherent integration to obtain adequate representation of the signal. The resulting measurement technique, which employs coherent cross correlation with coherent integration, is described below.

(U) Because of the need to perform coherent integration as well as to accommodate Doppler effects, fast Fourier transform techniques (FFT) were employed. These techniques provided two

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

constraint on the measurement process. First, the coherent integration time was limited to about 30 sec because of the memory limitations of the processing equipment. Second, the transmission format was selected to have an integer number of sequence periods contained in the transform interval, so that a clear alignment of the signal and FFT spectral lines would be obtained. Once these two constraints were satisfied, the application of FFT techniques allowed straightforward measurement of both the spatial stability and the input signal-to-noise ratio.

(U) The transmission for the experiment was a 31-digit linear, maximal sequence with 15 carrier cycles per digit. Modulation of the 150-hz carrier was uncomplicated by complementary phase techniques, so as to yield a high-level carrier and yet retain a higher total power than with amplitude modulation. The transmission is given by

$$m(t) = \sum_{i=0}^{30} a(i) \cos 2\pi f_c t + [1 - a(i)] \sin 2\pi f_c t \quad (68)$$

where $f_c = 150$ hz is the carrier frequency, $T = 10.111$ sec is the digit duration, $a(i)$'s are the all sequence coefficients, and $U(t)$ is the unit step function. This transmission has the same power spectrum as an amplitude-modulated sequence of the same structure, but it has approximately 3 db higher total power. Because $m(t)$ is periodic, with a period of 1.22857 sec, its spectrum has a fine spacing of 0.752125 hz. The transmission has a zero-to-zero bandwidth of 46.667 hz, determined by the digit duration, T .

(U) After initial analog bandpass filtering to a 50-hz band about 250 hz, the received signal $r(t)$ is sampled at a rate of $4f_m$ where f_m is the receiver center frequency ($f_m = 250$ hz for zero Doppler). The resulting samples were compressed in the manner defined in Eqs. (26) and (27), but with $K_s = 10$. This reduces the number of samples to agree with the sampling theorem requirements and yields 160 compressed samples per sequence period. For convenience in the subsequent discussions, these samples are considered in terms of 2,033 long, complex vectors, $[Z(k, \eta)]_i = 0, \dots, 2,031$, where the k indicates the k th transform interval. That is, the sample following $Z(k, 2,037)$, is $Z(k+1, 0)$, and so forth.

$$\text{Serr}(k) = \left(\frac{1}{1.22857} - \frac{22}{20.22857} \right); \quad (69)$$

$$= 0.000215 \text{ bits} \quad (70)$$

For the energetic lines near the carrier, this offset is less than half the FFT line spacing of 0.000205 hz, and it will be neglected in the subsequent discussion.

I. Operation of Zero Doppler

(D) To understand the operation of the measurement technique, first consider its operation with zero Doppler. Because the transform interval contains nearly 22 sequence periods, every 22nd transform spectral line from the carrier will contain signal energy. The intervening 21 transform lines will contain only noise energy. Consequently, a processing gain of 22 (13.6 db) can be achieved by considering only every 22nd transform spectral line about the carrier.

(D) Let $[Z(k, \eta)] = 1,024 \leq i \leq 1,023]$ be the discrete Fourier transform of the input vector $[x(k, \eta)]_i = 0, \dots, 2,031$ with the i index on $[Z(k, \eta)]$ selected so the $Z(k, 0)$ corresponds to the carrier line at zero Doppler. Define a new spectrum $[S(k, \eta)] = -32 \leq i \leq 31$ from $[Z(k, \eta)]$ by selecting every 22nd spectral line of $[Z(k, \eta)]$ as follows:

$$[S(k, \eta)] = Z(k, 22\eta); \quad -32 \leq i \leq 31 \quad (71)$$

From the discussion of the preceding paragraph, $[S(k, \eta)]$, will contain signal energy with a 13.6-db improvement in signal-to-noise ratio over that of $[Z(k, \eta)]$, because of the elimination of 21 lines containing noise alone.

(D) The measurement of spatial stability is accomplished by calculating the normalized cross

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

correlation coeff. $\rho_{z^*}(k)$, between the signal waveform in the k th transform interval with that of the $(k-1)$ th transform interval. Let $s(k, i)$, $i=0 \dots 127$, be the inverse discrete Fourier transform of the k th signal spectrum $S(k, i)$. The normalized cross-correlation function $\rho(k, j)$ between $s(k, i)$ and $s(k-1, i)$ is defined by

$$\rho(k, j) = \frac{\sum_{i=0}^{127} s(k, i)s(k-1, i+j)}{\sqrt{\sum_{i=0}^{127} s(k, i)^2} \sqrt{\sum_{i=0}^{127} s(k-1, i)^2}} \quad (72)$$

where the $(i+j)$ index is taken modulo 128 so that $\rho(k, j)$ is the result of a circular correlation. Because the transform length is not an exact multiple of the sequence period, $\rho(k, 0)$ does not give the correlation corresponding to exact alignment between the two waveforms. Consequently, a maximization process must be performed to determine the correlation coefficient, $\rho_z^*(k)$, which represents the medium spatial stability:

$$\rho_z^*(k) = \max_j |\rho(k, j)|; \quad 0 \leq j \leq 63 \quad (73)$$

The coefficient $\rho_z^*(k)$ has the same ambiguity in terms of pure time shift that the $\rho_z^*(i)$ coefficients had in the preliminary experiments. As before, this ambiguity is known to be insignificant, on the basis of other experimental data.

(U) To properly interpret the correlation coefficient, $\rho_z^*(k)$, a quantitative knowledge of the signal-to-noise ratio of both the $S(k, i)$ and $S(k-1, i)$ vectors is needed. The signal power $SP(k)$ can be computed directly from the signal spectrum $S(k, i)$.

$$SP(k) = \sum_{i=-N}^N |S(k, i)|^2 \quad (74)$$

To determine the noise power, the power in a transform spectral line in between the signal lines is calculated.

$$NP(k) = \sum_{i=-N}^N |Z(k, 2i+1)|^2 \quad (75)$$

If it is assumed that the noise is white (at least relative to the signal line spacing of 0.752691 Hz), $NP(k)$ gives a measure of the noise content of $S(k, i)$. Consequently, the signal-to-noise ratio $SNR_{in}(k)$ of $S(k, i)$ is simply the ratio of $SP(k)$ to $NP(k)$.

$$SNR_{in}(k) = \frac{SP(k)}{NP(k)} \quad (76)$$

The input signal-to-noise ratio $SNR_{in}(k)$ is 22 times (13.4 dB) worse than $SNR_{out}(k)$.

$$SNR_{out}(k) = \frac{1}{22} SNR_{in}(k) \quad (77)$$

Thus, both the input and output signal-to-noise ratios can be quantitatively measured in each transform interval.

2. Operation with Nonzero Doppler

(U) Measurement of the correlation coefficient $\rho_z^*(k)$ and the input and output signal-to-noise ratios is not significantly more difficult when the Doppler is nonzero. Let f_c' be the Doppler-shifted carrier frequency

$$f_c' = \frac{f_c}{1 - v/c} \quad (78)$$

If the difference between f_c' and the receiver center frequency, f_{rec} , is small, then the effect of Doppler on the received signal is approximately a frequency translation. Such a frequency translation acts as a fixed offset between the zero-Doppler location of the signal spectral lines and the actual received spectral lines.

(U) Consider the situation where f_c' and f_{rec} differ by Δf Hz.

$$\Delta f = f_c' - f_{rec} \quad (79)$$

Then if the effects of Doppler are considered as a frequency translation, the signal spectrum will be displaced by r' transform spectral lines.

$$r' = \frac{\Delta f}{0.004180} \quad (80)$$

In general, the displacement r' will not be an integer. The integer offset, r'' , to the closest transform spectral line can be found from

$$r'' = [r' + 0.5] \quad (81)$$

where the square brackets $[x]$ indicate the greatest integer part of x . In subsequent discussion, r'' is called the vernier frequency index.

(U) Given the vernier frequency index, r'' , Eq. (71) for the signal spectrum can be modified to incorporate the effects of Doppler.

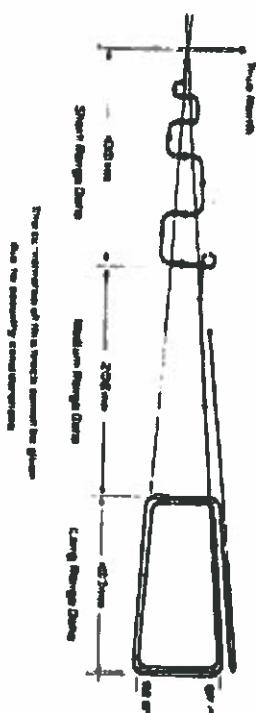

CONFIDENTIAL

UNCLASSIFIED

UNCLASSIFIED

CONFIDENTIAL

Figure 18. Vessel track for the January 1974 experiments. (Figure modified.)

$$S(k, r) = Z(k, 22r + r^*) \quad (82)$$

Similarly, Eq. (75) for the noise power becomes

$$NP(k) = \sum_{n=1}^{N/2} |Z(k, 22n + 11 + r^*)|^2 \quad (83)$$

With these two modifications of the zero-Doppler equations, the derivation of the correlation coefficient $\rho_r^*(k)$ and the signal-to-noise ratios remain valid in the presence of Doppler.

(ii) The significant remaining problem is the determination of the carrier frequency index, r^* , by the measurement system. One approach is to search the received signal spectrum $Z(k, r)$ for the largest signal line (presumably the carrier at $k_0 + r^*$) and calculate M and r^* . Unfortunately, selective fading due to multipath will occasionally reduce the carrier level below that of the adjacent sidebands, and the system will obtain an incorrect value for r^* .

(iii) To avoid this problem, the measurement system determined r^* on the basis of best likelihood \hat{r} (maximum-likelihood ratio). Specifically, the following quantity is calculated

$$\text{SNR}_m(k, r) = \frac{\sum_{n=1}^{N/2} |Z(k, 22n + r)|^2}{\sum_{n=1}^{N/2} |Z(k, 22n + 11)|^2} \quad (84)$$

for $-10 \leq r \leq 11$. The expression $\text{SNR}_m(k, r)$ given in Eq. (84) is simply the output signal-to-noise ratio if r were the correct receiver frequency index. The range of r is constrained to be within one signal-line separation (0.752691 Hz, or approximately a 6.4-knot Doppler uncertainty), as spacing of the signal spectral lines. In actual measurements, the receiver frequency, f_m , is

adjusted to be within about 0.1 Hz of f_0^* , so this constraint in r is not a problem.

(iv) To determine the value of r^* , the processor selected the value of r that yielded the highest value of $\text{SNR}_m(k, r)$. Because $\text{SNR}_m(k, r)$ is based on the broadband signal spectrum and not on any single spectral line, the resulting frequency offset, r^* , is not disturbed by selective fading. Given r^* , the calculation of $\rho_r^*(k)$ and the signal-to-noise ratios is easily accomplished. Indeed, the measurement system performed all necessary calculations in real time, producing new values of $\rho_r^*(k)$ and $\text{SNR}_m(k)$ every 29.257143 sec.

3. Experimental Results

(i) During January 1974, the HK60 acoustic source was towed in the deep ocean between Eleuthera and Bermuda. The approximate vessel track relative to the hydrophone is shown in Fig. 18. Signals from the source were received at a fixed hydrophone and processed with the coherent integration technique described above. The ranges of the experiment varied from 0 to 400 nmi, with most of the experiment being conducted at ranges between 300 and 400 nmi. During the experiment, the vessel speed was maintained at approximately 6 knots.

(ii) The digital processor was in nearly continuous operation during the 12 days of the experiment, yielding correlation coefficients, $\rho_r^*(k)$ and signal-to-noise ratios every 29.257143 sec. These and other results were recorded on digital magnetic tape and simultaneously plotted on a multiview recorder. Figure 19 depicts an unnotated typical multipoint plot from the processor. As in the M5 and M6 experiments, this plot was an important aid in maintaining quality control during the experiment.

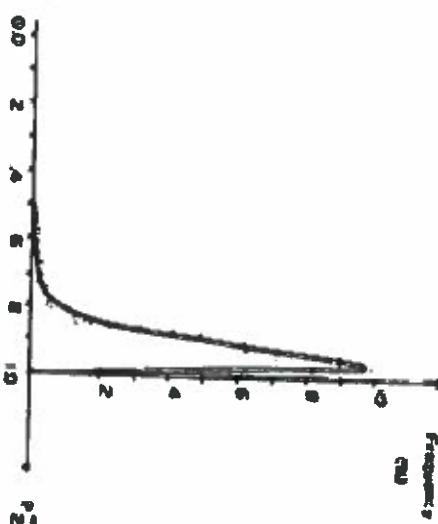

Figure 20b. Histogram of SNR from the January 1974 (medium-range data. (Figure unclassified.)

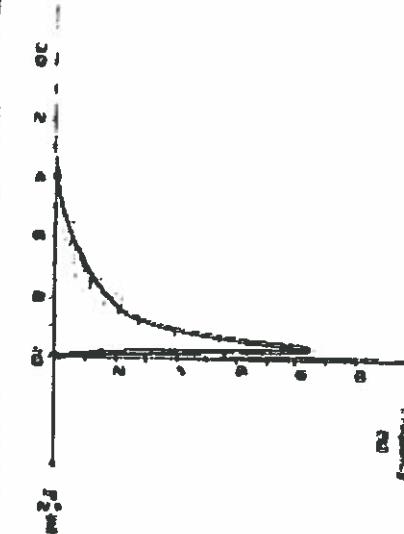

Figure 20c. Histogram of SNR from the January 1974 long-range data. (Figure unclassified.)

(U) Data from the January 1974 experiment can be divided into three sets. The first set, called the "short range," includes data in which the source was going from 0 to 100 nmi. The second set, called the "medium range," includes data in which the source was going from 100 nmi to 200 nmi. Because of the severe range changes, data in these two sets represent measurements over a wide variety of transmission conditions. The third set, which is the largest, includes the data taken at ranges between 300 and 400 nmi and is referred to as the "long range" data. No correction for changes in range has been applied to any of the three data sets.

(U) Figure 20a depicts a histogram of the received

signal-to-noise ratio in decibels for the short-range data. The mean signal-to-noise ratio is 0.5 db, with a standard deviation of 4.3 db. Figure 20b depicts an analogous histogram for the medium-range data. For the medium-range data the mean signal-to-noise ratio is -0.9 db, with a standard deviation of 6.2 db. Figure 20c depicts a histogram for the long-range data with a mean of -1.0 db and a standard deviation of 4.4 db. The reduced standard deviation for the long-range data as opposed to the medium-range data is due to the relative uniformity of the long-range data in terms of transmission conditions.

(U) Spatial stability was evaluated by means of

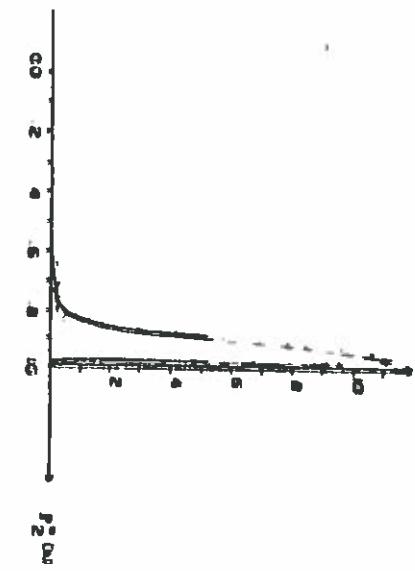

Figure 21b. Histogram of $R^2(k)$ for new Doppler track. (Figure not normalized.)

histograms of $R^2(k)$, much as in the M5 and M6 experiments. Because noise can reduce the values of $R^2(k)$, making the measurement incorrect, a threshold was placed on the output signal-to-noise ratios of both $S(k, \tau)$ and $S(k - 1, \tau)$. This threshold required that the signal-to-noise ratios on both $S(k, \tau)$ and $S(k - 1, \tau)$ be greater than ± 10 dB if $R^2(k)$ was to be included in the data. When this requirement is applied, approximately 100 percent of the short-range data, 55 percent of the medium-range data, and 46 percent of the long-range data meet or exceed the threshold.

(f) Figure 21a depicts the histogram of correlation coefficients $R_c(k)$ for the short-range data. The mean correlation coefficient is 0.855, with a standard deviation of 0.138. In Figs. 21b and 21c, the corresponding histograms for the medium- and long-range data are shown. The mean correlation coefficient for the medium data is 0.913, with a standard deviation of 0.112. The mean correlation for the long-range data is 0.916 with a standard deviation of 0.051. The slight increase in mean correlation value for the long-range data is not considered to be significant.

VI. FUTURE APPLICATIONS AND CONCLUSIONS

(1) The dependence of spatial stability on the relative direction of the spatial displacement is of interest. The prevailing conjecture is that the stability will be less on a full Doppler track than on a *short* Doppler track. Figure 22a depicts a $R^2(k)$ histogram for the long-range data on a full Doppler track; Fig. 22b corresponds to a zero

Doppler track. The mean correlation coefficient for the zero Doppler data is 0.925, with a standard deviation of 0.051; for the full Doppler track the mean and standard deviations are 0.914 and 0.053, respectively. Thus, the January 1974 data do not indicate any dependence of spatial stability on the direction of displacement, at least for long ranges.

(2) The results of the January 1974 spatial stability experiment are remarkably similar to those obtained in the M5 and M6 experiments. Figures 21a and 21b compare the overall (short medium, and long range) histogram of correlation coefficients obtained in the January 1974 experiment with a typical one-day histogram from the M6¹ experiment. Although the measurement interval was shorter in the January experiment than in the M6¹ experiment (29 sec versus 61 sec), the similarities in the histograms are amazing, considering the differences in location and range between the two experiments.

A CONCLUDING

¹ The effectiveness of coherent matched-filter techniques was demonstrated in *fixed-air* experiments in the Straits of Florida. The application of coherent integration over time intervals of the order of one minute yielded satisfactory operation

UNCLASSIFIED

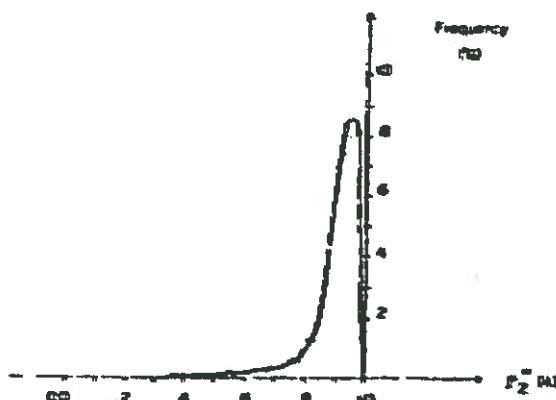

Figure 23a. Comparison of correlation coefficient histograms: overall p_r^2 (b) hi-sogram from January 1974 experiment. (Figure unclassified.)

at input signal-to-noise ratios below 0 db. By matched filtering of the received signal, the effects of selective fading and intersymbol interference due to multipath were reduced. Massive amounts of data (over 4,000 hours) on system performance add significance to the results obtained.

(c) To apply coherent, matched-filter techniques to the submarine communication problem, an understanding of the medium's spatial, as well as temporally, stability is required. A ten-day experiment in the Atlantic between Eleuthera and Bermuda with a towed source and a fixed hydrophone was conducted to measure spatial stability. The results from this experiment indicated the presence of sufficient spatial stability over intervals of at least 30 sec at six knots, at ranges from 0 to 400 nautical miles.

(d) The combination of fixed-site communication system results and the spatial stability measurements establishes the feasibility of coherent, matched-filter techniques for submarine communications. Advantages to be gained from these techniques include reliable operation at low signal-to-noise ratios and under varying propagation conditions. Further, randomized transmission formats can be employed to reduce the detectability of the communication signal. Because the technology required to implement coherent, matched-filter techniques is readily available, their application to submarine communications should be initiated.

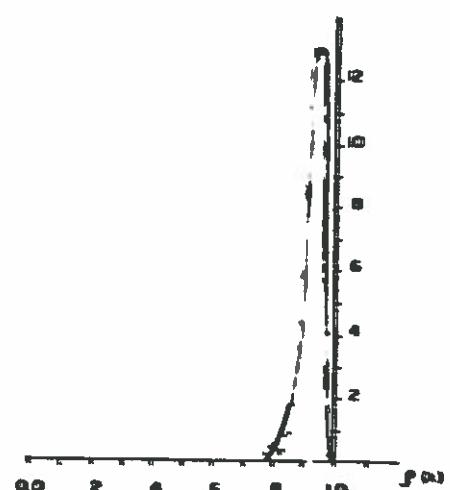

Figure 23b. Comparison of correlation coefficient histograms: one-day p_r^2 histogram from M6C experiment. (Figure unclassified.)

1. Subsidary Conclusions

(U) The experimental program yielded several secondary results that should be considered in subsequent submarine communication system design.

(c) First, the acoustic medium exhibits significant variance in input signal-to-noise ratio SNR_m , even under fixed-site conditions. Standard deviations of SNR_m of the order of 5 db can generally be expected. These variations require that any reliable communication system be able to operate successfully over a wide range of input signal-to-noise ratios. Coherent, matched-filter systems satisfy this requirement more closely than the incoherent systems currently in use.

(d) Second, impulsive noise must be accounted for in any system in which low ($PE < 0.001$) bit error probabilities are required. The presence of infrequent, high-energy noise pulses can limit the error probability to a fixed level, independent of the average input signal-to-noise ratio. Soft limiting of the receiver input in conjunction with error-correcting codes can be used to overcome this limitation.

2. SUGGESTED APPLICATION

(c) The M5 and M6 communication systems were designed specifically for the evaluation of

CONFIDENTIAL

K_1	K_2	Rate, bits/sec	Minimum Operating SNR, db	Range, m
100	40	1.0	-4	<100
200	20	0.5	-7	<100
.50	10	0.25	-10	>100
1.00	4	0.1	-14	>100

coherent, matched-filter techniques. Consequently, their structure lack many features required of a practical submarine communication system. For example, the transmission in the M5 and M6 systems is continuous, and synchronization is performed by the operator. Neither of these characteristics is acceptable in practice. The purpose of this section is to suggest one realization of a coherent, matched-filter communications system that is suitable for operational use. Only the structure of the transmission and the expected performance characteristics are given here. The details of the receiver processing and implementation will be available in the future.

(v) Although good performance at low signal-to-noise ratios and under varying multipath conditions is necessary for any submarine communication system, other operationally important requirements must also be considered. Two such requirements are that the transmission be of limited duration and that it be detection resistant. The first requirement precludes blanking of passive user systems on the transmitting platform, while the second reflects the need to prevent detection or localization of the transmitting platform.

(vi) The M7 system, described below, has been designed to provide an application of coherent, matched-filter techniques that satisfy the requirements previously stated. Specifically, the M7 system utilizes a burst type of transmission with a randomized format. The structure of the transmission is based entirely on an arbitrary random binary sequence that can be changed on a daily basis if desired. The only constraint on this sequence is that it must be known to both the

transmitter and receiver and have the same statistical properties as other random sequences.

(vii) In the M7 system, the probe and information components are phase multiplexed instead of time multiplexed as in the M5 and M6 systems. Let $s(t)$ be a low-pass signal of duration T and let f_c be the carrier frequency, then the M7 transmission is given by

$$s(t) = \sum_{i=0}^{K-1} q_r(i)s(t-iT) \cos 2\pi f_c t + q_i(i)s(t-iT) \sin 2\pi f_c t \quad (55)$$

The first term in the sum is the probe component and the second is the information component. The coefficients $q_r(i)$, $q_i(i)$ (± 1) are derived from a random binary sequence $q(t)$ and the information component as indicated below.

(viii) Let $q(t)_{[i+1]}$ be a random binary sequence of length $2K_1$. The coefficients for the probe component $q_r(i)$ are simply the $q(t)$'s of even index.

$$q_r(i) = q(2i); \quad i=0 \dots K-1 \quad (56)$$

Assume that K_1 information bits $a(t)$ are to be transmitted. Further, assume that K_2 is a factor of K_1 so that $K_1 = K_2 K_0$ for some integer K_0 . Then the coefficients for the information component are given by

$$q_i(i) = (i/K_0) q(2i+1); \quad i=0 \dots K_0-1 \quad (57)$$

where $[x]$ indicates the integer part of x . Thus, $q_i(i)$ is formed by the modulation of $q(t)$ for odd indices by the information values in groups of K_0 digits.

(ix) Since both coefficients $q_r(i)$ and $q_i(i)$ are derived from a random sequence, $q(t)$, the transmission $s(t)$ can be expected to be free from periodicities or strong spectral components. If the input signal-to-noise ratio of an intercept receiver is below 0 db, the detectability of the M7 transmission will be very low. If the input signal-to-noise ratio of the intercept receiver is above 0 db, conventional power measurement techniques are applicable. Consequently, the M7 technique (or any other) can be considered detection resistant only if the intercept receiver is denied an adequate signal-to-noise ratio, that is, be beyond a certain range.

(U) To provide an illustration of the performance to be expected of the M17 system, a specific priorized example is given. Assume that the system bandwidth is 100 Hz and that the transmission duration is limited to 40 sec. Let σ_n^2 be a 10-sec rectangular pulse, so that the spectrum of $\sigma(t)$ fills the system bandwidth. Then, K_c equals 4,000. Table 5 gives the system performance for several choices of K_c . The relation marked "minimum operating SNR" gives the input signal-to-noise ratio expected to yield a bit probability of error of 0.001. This signal-to-noise ratio is obtained by taking the theoretical signal-to-noise ratio required to obtain such performance and then adding a +6 dB differential to account for nonidealities. Note the low signal-to-noise ratios for which the 0.001 error probability is expected.

ACKNOWLEDGMENTS
